The Effect of Fertility on Mothers' Labor Supply over the Last Two Centuries

Daniel Aaronson, Rajeev Dehejia, Andrew Jordan, Cristian Pop-Eleches, Cyrus Samii, and Karl Schulze

August 2017

Abstract

This paper documents the evolving impact of childbearing on the work activity of mothers. Based on a compiled dataset of 441 censuses and surveys between 1787 and 2015, representing 103 countries and 48.4 million mothers, we document three main findings: (1) the effect of fertility on labor supply is small and typically indistinguishable from zero at low levels of development and economically large and negative at higher levels of development; (2) this negative gradient is remarkably consistent across histories of currently developed countries and contemporary cross-sections of countries; and (3) the results are strikingly robust to identification strategies, model specification, data construction, and rescaling. We explain our results within a standard labor-leisure model and attribute the negative labor supply gradient to changes in the sectoral and occupational structure of female jobs as countries develop.

The views expressed in this paper are not necessarily those of the Federal Reserve Bank of Chicago or the Federal Reserve System.

I. Introduction

The relationship between fertility and female labor supply is widely studied in economics. For example, the link between family size and mothers' work decisions has helped explain household time allocation and the evolution of women's labor supply, particularly among rapidly growing countries in the second half of the 20th century (Carlinger, Robinson, and Tomes 1980; Angrist and Evans 1998; Del Boca, Pasqua, and Pronzata 2005; Cristia 2008; Bruijns 2014; and Hupkau and Leturcq 2016). Development economists relate the fertility-work relationship to the demographic transition and study its implications on economic growth (Bloom, Canning, and Sevilla 2001). Yet despite the centrality of these issues in the social sciences, there is no unified evidence on whether this relationship has evolved over time and with the process of economic development.

Our contribution is to provide such evidence that spans not only a broad cross-section of countries at various stages of development but historical examples from currently developed countries dating back to the late 18th century.[1] To provide consistent estimates over time and space, we use two common instrumental variables strategies: (i) twin births introduced by Rosenzweig and Wolpin (1980) and applied repeatedly since (Bronars and Grogger 1994; Black, Devereux, and Salvanes 2005; and Caceres-Delpiano 2006) and (ii) the gender composition of the first two children (Angrist and Evans 1998). We implement these estimators using four large databases of censuses and surveys: the International Integrated Public Use Micro Sample (IPUMS), the U.S. IPUMS, the North Atlantic Population Project, and the Demographic and Health Surveys. Together, the data cover 441 country-years, and 48.4 million mothers, stretching from 1787 to 2015 and, consequently, a large span of economic development.

A natural starting point in thinking about the fertility-labor supply relationship is Angrist and Evans (1998). Based on U.S. IPUMS data from 1980 and 1990, Angrist and Evans document a negative effect of fertility on female labor supply using both gender mix and twin births as instruments for subsequent children, a result also established by Bronars and Grogger (1994).[2] Alternative instruments that rely on childless mothers undergoing infertility treatments in the U.S. and Denmark (Cristia 2008 and Lundborg, Plug, and Rasmussen 2016) or natural

[1] A related paper by Chatterjee and Vogl (2017) studies how fertility responds to long-run growth.
[2] For discussions of the validity of various fertility instruments, see for example Rosenzweig and Wolpin (2000), Hoekstra et al. (2007), Angrist, Lavy, and Schlosser (2010), and Bhalotra and Clarke (2016). Clarke (2016) provides a useful summary of the empirical literature.

experiments like the introduction of birth control pills (Bailey 2013) or changes in abortion legislation (Bloom et al. 2009 and Angrist and Evans 1996) similarly conclude that children have a negative effect on their mother's labor supply or earnings. This instrument-invariant robustness is particularly notable since each IV uses a somewhat different subpopulation of compliers to estimate a local average treatment effect. That the results are consistent suggests wide external validity (Angrist, Lavy, and Schlosser 2010; Bisbee et al. 2017).

However, we show that the negative relationship between fertility and mother's work behavior holds only for countries at a later stage of economic development. At a lower level of income, including the U.S. and Western European countries prior to WWII, there is no causal relationship between fertility and mother's labor supply. The lack of a negative impact at low levels of development corresponds with Aguero and Marks' (2008, 2011) study of childless mothers undergoing infertility treatments in 32 developing countries and Godefroy's (2017) analysis of changes to women's legal rights in Nigeria.[3] Strikingly, combining U.S historical data with data from a broad set of contemporary developing countries, we find that the negative gradient of the fertility-labor supply effect with respect to economic development is remarkably consistent across time and space. That is, women in the U.S. at the turn of the 20th century make the same labor supply decision in response to additional children as women in developing countries today. Moreover, we show that the negative gradient is exceedingly robust to a wide range of data, sampling, and specification issues, including alternative instruments, development benchmarks, initial family sizes, sample specification criteria, conditioning covariates including those highlighted by Bhalotra and Clarke (2016), and measures of mother's labor supply, as well as rescaling the estimates to account for varying secular rates of labor force participation and a variety of other adjustments to make our data historically consistent.

The empirical regularities we describe support a standard labor-leisure model augmented to include a taste for children. As wages increase during the process of development, households face an increased time cost of fertility but also experience increased income. With a standard constant elasticity of substitution utility function, the former effect dominates as countries develop, creating a negative gradient.

Indeed, in exploring the mechanism behind our result, we document that the income

[3] In addition, Heath (2017) reports an economically small effect of fertility on women working using non-experimental evidence from urban Ghana.

effect from rising wages is likely invariant to economic development but the substitution effect falls from zero to negative and is economically important as real GDP per capita increases. We argue that the declining substitution effect arises from changes in the sectoral and occupational structure of female jobs, as in Goldin (1995) and Schultz (1991). In particular, as economies evolve, women's labor market opportunities transition from agricultural and self-employment to urban wage work. The latter tends to be less compatible with raising children and causes some movement out of the labor force (Jaffe and Azumi 1960; McCabe and Rosenzweig 1976; Kupinsky 1977; Goldin 1995; Galor and Weil 1996; Edwards and Field-Hendrey 2002; and Szulga 2013). In support of this channel, we show that the negative gradient is steeper among mothers with young children that work in non-professional and non-agricultural wage-earning occupations (e.g., urban wage work). Moreover, a growing literature documents a causal relationship between access to child care or early education and the propensity of mothers to work (Berlinski and Galiani 2007; Baker, Gruber, and Milligan 2008; Cascio 2009; Havnes and Mogstad 2011; Fitzpatrick 2012; and Herbst 2017), a finding that is consistent with leaving the workforce when labor market opportunities become less compatible with child rearing.

Our main empirical findings have important implications both for understanding the historical evolution of women's labor supply and the relationship between the demographic transition and the process of economic development. As Goldin (1995) documents in her comprehensive study of women's work in the 20th century, women's labor supply follows a U-shape over the process of economic growth, first declining before eventually increasing. Our results suggest that declining fertility may have contributed to the upswing in women's labor supply in much of the developed world during the second half of the century. Moreover, family policies (Olivetti and Petrolgolo 2017) and childcare costs (Del Boca 2015; Herbst 2015; and Kubota 2016) likely played a role. At the other end of the economic development spectrum, our results suggest that the demographic transition to smaller families probably does not have immediate implications for women's labor supply and growth. This in turn reinforces a claim in the demographic transition literature (Bloom, Canning, and Sevilla 2001) that family planning policies are unlikely to enhance growth through a labor supply channel (although such policies could still be desirable for other reasons).

Our paper is organized as follows. We begin by sketching a model highlighting the key mechanism driving fertility's impact on labor supply. Section III explains our empirical strategy, followed in section IV by a description of the data. Section V presents our findings, along with a series of robustness checks. Section VI analyzes potential channels for our results, and section VII briefly concludes.

II. Sketch of a Model

We believe the differential female labor supply response to children over the development cycle can be explained within a standard labor-leisure model. In particular, consider a constant elasticity of substitution (CES) utility function defined over consumption *c*, leisure *d*, and fertility *n*:

(1) $$U(c,d,n) = \left[\gamma(c+c_0)^{\rho} + \alpha d^{\rho} + \beta\left(\frac{n}{N}\right)^{\rho}\right]^{1/\rho}$$

where c_0 <0 is subsistence consumption and utility from fertility is relative to potential reproductive capacity *N*. Equation (1) is a CES variant of the model used by Bloom et al. (2009). Total time (normalized to 1) is allocated between leisure *d*, childcare *bn* (where *b* is the time cost per child), labor *l*, and non-market household work ε:

(2) $$1 = l + d + bn + \varepsilon$$

Assuming households do not save, consumption is derived directly from earned income:

(3) $$c = wl.$$

Substituting equations (2) and (3) into (1), we obtain the household utility function:

(4) $$V(l,n) = \left[\gamma(wl+c_0)^{\rho} + \alpha(1-l-bn-\varepsilon)^{\rho} + \beta\left(\frac{n}{N}\right)^{\rho}\right]^{1/\rho}.$$

The first order conditions are:

(5) $$\partial V/_{\partial l} = \frac{1}{\rho}v^{\left(\frac{1}{\rho}-1\right)}[\rho\gamma w(wl+c_0)^{\rho-1} - \alpha\rho(1-l-bn-\varepsilon)^{\rho-1}] = 0$$

$$\partial V/_{\partial n} = \frac{1}{\rho}v^{\left(\frac{1}{\rho}-1\right)}[-\alpha\rho b(1-l-bn-\varepsilon)^{\rho-1} + \beta\rho N^{-\rho}n^{\rho-1}] = 0$$

where $v \equiv \left[\gamma(wl+c_0)^{\rho} + \alpha(1-l-bn-\varepsilon)^{\rho} + \beta\left(\frac{n}{N}\right)^{\rho}\right]$. Re-arranging yields:

(6)

$$l = \frac{\left(\alpha^{\theta} - \alpha^{\theta}\epsilon - w^{\theta}\gamma^{\theta}c_0\right) - \alpha^{\theta}bn}{w^{\theta+1}\gamma^{\theta} + \alpha^{\theta}}$$

$$n = \frac{\alpha^{\theta}b^{\theta}(1-\varepsilon-l)}{\beta^{\theta N^{-\rho\theta}} + \alpha^{\theta}b^{\theta+1}},$$

where $\theta \equiv 1/(\rho-1)$. Note that in the solution:

(7)

$$\frac{\partial l}{\partial n} = -\frac{\alpha^{\theta} b}{w^{\theta+1}\gamma^{\theta} + \alpha^{\theta}} < 0$$

and $\partial^2 l/\partial n \partial w < 0$ if $\rho \in (0,1)$ or the elasticity of substitution is between (0,∞). Of note, the model predicts the effect of fertility on labor supply becomes more negative as the wage increases. As the wage increases, the agent experiences both a substitution and income effect. The former arises because an increase in the wage causes the price of leisure and the time-cost of children to also increase, leading to a substitution into labor and out of children. Higher wages also increase income, which moves households away from labor and toward children. When the elasticity of substitution is positive, the substitution effects tends to dominate, increasing the responsiveness of labor to fertility as the wage goes up.

In a small number of low-income countries, including pre-WWI U.S., we estimate a modest positive labor supply response to children. While equation (7) predicts a negative response, a positive result is possible with a simple extension of the model. Suppose there is a consumption (e.g., food) cost to children so $c = wl - kn$, and for simplicity set c_0 and ε to zero. The first-order condition with respect to labor, with rearrangement, now becomes:

(8)

$$l = \frac{\alpha^{\theta} + n\left(w^{\theta}\gamma^{\theta}k - \alpha^{\theta}b\right)}{w^{\theta+1}\gamma^{\theta} + \alpha^{\theta}}.$$

In this case $\partial l/\partial n > 0$ is consistent with $k > \alpha^{\theta} b/\gamma^{\theta} w^{\theta}$. An increase in fertility implies an increased time cost but also a reduction in consumption, making increased labor more valuable. Since $\theta < 0$, if the wage or the time cost of children are sufficiently low relative to the consumption cost, mothers optimally increase labor. In this case, $\partial^2 l/\partial n \partial w < 0$ without further assumptions, so we would continue to expect a negative gradient of the fertility-labor relationship with respect to the wage.[4]

III. Empirical Strategy

Our empirical analysis adopts the standard approach of exploiting twin births and gender composition as sources of exogenous variation in the number of children to identify the causal effect of an additional child on the labor force activity of women (Rosenzweig and Wolpin 1980; Bronars and Grogger 1994; Angrist and Evans 1998; and Black, Devereux, and Salvanes 2005).

---

[4] Note $\text{sgn}(\partial^2 l/\partial n \partial w) = \text{sgn}\left(-\gamma^{\theta} k \gamma w^{\theta} + \theta k w^{-1}\alpha^{\theta} + (\theta+1)\alpha^{\theta}\right) = -1$ if $\rho \in (0,1)$..

In particular, for twin births, consider a first stage regression of the form:

(9) $z_{ijt} = \gamma S_{ijt} + \rho w_{ijt} + \pi_{jt} + \mu_{ijt}$

where z_{ijt} is an indicator of whether mother *i* in country *j* at time *t* had a third child, the instrument S_{ijt} is an indicator for whether the second and third child are the same age (twins), w_{ijt} is a vector of demographic characteristics that typically include the current age of the mother, her age at first birth, and an indicator for the gender of the first child, and π_{jt} are country-year fixed effects. γ measures the empirical proportion of mothers with at least two children who would not have had a third child in the absence of a multiple second birth.

The local average treatment effect (LATE) among mothers with multiple children is identified from a second stage regression:

(10) $y_{ijt} = \beta z_{ijt} + \alpha w_{ijt} + \theta_{jt} + \varepsilon_{ijt}$

where y_{ijt} is a measure of labor supply for mother *i* in country *j* at time *t* and β is the IV estimate of the pooled labor supply response to the birth of twins for women with at least one prior child.[5] Our baseline twin estimates condition on one child prior to the singleton or twin so that all mothers have at least two children, as in Angrist and Evans (1998). This restriction provides a family-size-consistent comparison so that both the same-gender and twins IV study the effect of a family growing from two to three children.

While twins are a widely-used source of variation for studying childbearing on mothers' labor supply, it is by no means the only strategy in the literature. Perhaps the leading alternative exploits preferences for mixed gender families (Angrist and Evans 1998). In particular, Angrist and Evans estimate a first-stage regression like equation (9) but, for S_{ijt}, substitute twin births for an indicator of whether the first two children of woman *i* are of the same gender (boy-boy or girl-girl). Again, the sample is restricted to women with at least two children and γ measures the likelihood that a mother with two same gendered children is likely to have additional children relative to a mother with a boy and a girl.

Both twins and same gender children have been criticized as valid instruments on the grounds of omitted variables biases. Twin births may be more likely among healthier and wealthier mothers and can consequently vary over time and across geographic location (Rosenzweig and Wolpin 2000; Hoekstra et al. 2007; Bhalotra and Clarke 2016; and Clarke

[5] The reported estimates of β are weighted by the household weights supplied by the various surveys or censuses, normalized by the number of mothers in the final regression sample.

2016). Rosenzweig and Zhang (2009) also argue that twin siblings may be cheaper to raise, leading to a violation of the exclusion restriction. While the same gender instrument has proven quite robust for the U.S. and other developed countries (Butikofer 2011), there are many reasons to be cautious in samples of developing countries (Schultz 2008). Among other factors, households may practice either sex selection or selective neglect of children based on gender (Ebenstein 2010 and Jayachandran and Pande 2015).

We adopt the broad view of Angrist, Lavy, and Schlosser (2010) that the sources of variation used in various IV strategies are different and, therefore, so are the biases. As such, each IV provides a specification check of the other. In this spirit, we also provide a series of LATE estimates that show a) twin results at alternative family parities, b) twins results of the same gender versus mixed gender,[6] c) findings from a third instrument introduced by Klemp and Weisdorf (2016), which relies on exogenous variation in the timing of first births, and d) directly employ the methodology in Angrist, Lavy, and Schlosser (2010) that combines multiple IV estimates. Additionally, to the extent possible, we show how our results vary when we control for education and health measures such as height and body mass index that have been highlighted as key determinants of twin births (Bhalotra and Clarke 2016).

The literature analyzes a number of measures of y_{ijt}, including whether the mother worked, the number of hours worked, and the labor income earned. These measures are sometimes defined over the previous year or at the time of the survey. In order to include as wide a variety of consistent data across time and countries as possible, we typically focus on the labor force participation (LFP) of mothers at the time of a census or survey. When LFP is unavailable, especially in pre-WWII censuses, we derive LFP based on whether the woman has a stated occupation. Section V.f.3 discusses the robustness of the results to several alternative labor market measures, including mismeasurement of occupation-based LFP (Goldin 1990).

In concordance with much of the literature, our standard sample contains women aged 21 to 35 with at least two children, all of whom are 17 or younger. We exclude families where a child's age or gender or mother's age is imputed. We also drop mothers who gave birth before

[6] Monozygotic (MZ) twinning is believed to be less susceptible to environmental factors. Hoekstra et al. (2007) provides an excellent survey of the medical literature. Since we cannot identify MZ versus dizygotic (DZ) twins in our data, we take advantage of the fact that MZ twins are always the same gender, whereas DZ twins share genes like other non-twin siblings and therefore are 50 percent likely to be the same gender.

age 15, live in group quarters, or whose first child is a multiple birth.[7] It is worth emphasizing that the restrictions on mother's (21-35) and child's (under 18) age may allay concerns about miscounting children that have moved out of the household.[8] We also experiment with even younger mother and child age cut-offs, which additionally provide some inference about difference in the labor supply response to younger and older offspring. Further sample statistics, as well as results when these restrictions are loosened, are provided in the Appendix.

We present our results stratified by time, country, level of development, or some combination. The prototypical plot stratifies countries-years into seven real GDP per capita bins (in 1990 U.S. dollars): under $2,500, $2,500-5,000, $5,000-7,500, $7,500-10,000, $10,000-15,000, $15,000-20,000, and over $20,000. To be concrete, in this example, all country-years where real GDP per capita are, say, under $2,500 in 1990 U.S. dollars are pooled together for the purpose of estimating equations (9) and (10). Similarly, countries with real GDP per capita between $2,500 and $5,000 are also pooled together for estimation, and so on. The plots report estimates of γ and β, and their associated 95 percent confidence interval based on country-year clustered standard errors, for each bin.

IV. Data

We estimate the statistical model using four large databases of country censuses and surveys.

a. U.S. Census, 1860-2010

The U.S. is the only country for which historical microdata over a long stretch of time is regularly available.[9] We use the 1 percent samples from the 1860, 1870, 1950, and 1970 censuses; the 5 percent samples from the 1900, 1960, 1980, 1990, and 2000 censuses; the 2010 American Community Survey (ACS) 5-year sample, which combines the 1 percent ACS samples for 2008 to 2012; and the 100 percent population counts from the 1880, 1910, 1920, 1930, and 1940 censuses.[10] Besides additional precision, the full count censuses allow us to stratify the sample (e.g. by states) to potentially take advantage of more detailed cross-sectional variation.

---

[7] These restrictions build on Angrist and Evans (1998). The final restriction takes care of rare cases of triplets.
[8] As a robustness check, we also use information about complete fertility when it is available.
[9] We use a sporadic time-series for Canada, UK, Ireland, and France as well.
[10] For information on the IPUMS samples, see Steven Ruggles, J. Trent Alexander, Katie Genadek, Ronald Goeken, Matthew B. Schroeder, and Matthew Sobek, ***Integrated Public Use Microdata Series: Version 5.0*** [Machine-readable database], Minneapolis: University of Minnesota, 2010. The 100 percent counts were generously provided to us by the University of Minnesota Population Center via the data collection efforts of ancestry.com. Those files have been cleaned and harmonized by IPUMS. The 1890 U.S. census is unavailable and U.S. censuses prior to 1860 do not contain labor force information for women. In some figures, we also report single-year estimates from the 1880 10 percent, 1930 5 percent, as well as the 1910, 1920, and 1940 1 percent random IPUMS samples.

IPUMS harmonizes the U.S. census samples to provide comparable definitions of variables over time. However, there are unavoidable changes to some of our key measures. For example, the 1940 census is the first to introduce years of completed schooling and earnings; therefore, when we show results invoking education or earnings, we exclude U.S. data prior to 1940. Perhaps most important, the 1940 census shifted our labor supply measure from an indicator of reporting any "gainful occupation" to the modern labor force definition of working or looking for work in a specific reference week. Fortunately, there does not appear to be a measurable difference in our results between these definitions in 1940 when both measures are available. Nevertheless, there is concern that women's occupations (Goldin 1990) as well as fertility (Moehling 2002) could be systemically under- or over-reported, especially in U.S. census samples for 1910 and earlier. We present a number of robustness checks meant to isolate these mismeasurement issues in Section V.f.3.[11]

For Puerto Rico, we use the 5 percent census samples from 1980, 1990, and 2000 and the 2010 Community Survey, which combines the 1 percent samples for 2008 to 2012.[12]

b. IPUMS International Censuses, 1960-2015

IPUMS harmonizes censuses from around the world, yielding measures of our key variables that are roughly comparable across countries and time. We use data from 212 of the 301 country-year censuses between 1960 and 2015 that are posted at the IPUMS-I website.[13] Censuses are excluded if mother-child links or labor force status is unavailable (83 censuses) or age is defined by ranges rather than single-years (6 censuses).[14]

c. North Atlantic Population Project (NAPP), 1787-1911

The North Atlantic Population Project (NAPP) provides 18 censuses from Canada,

[11] While the 1880, 1920, 1930, and 1940 full count censuses are fully harmonized across IPUMS samples, the 1910 full count census is not yet. For our purposes, the most important feature missing from the unharmonized data is child-mother linkages. Accordingly, we create family links ourselves using the IPUMS rules. The close correspondence between the estimates for the 1 percent and full count samples for 1910 suggests the absence of family linkages in the 1910 full count data is not a significant issue (see Figure 5).

[12] Prior Puerto Rican censuses are either missing labor force data or reliable information about real GDP per capita.

[13] This information is as of May 3, 2017, when we downloaded the data. The tabulations of available countries exclude the U.S. and Puerto Rico.

[14] Similar to the U.S., the international linking variables use relationships, age, marital status, fertility, and proximity in the household to create mother-child links. Sobek and Kennedy (2009) compute that these linking variables have a 98 percent match rate with direct reports of family relationships. However, we are not able to compute linkages that do not include relevant household information on relationship and surname similarity. Unfortunately, this affects some censuses from Canada and the U.K. The 1971 to 2006 Irish censuses use ages ranges for adults but not for children younger than 20. Therefore, twin children are identifiable and we do not exclude this data.

Denmark, Germany, Great Britain, Norway, and Sweden between 1787 and 1911. As with IPUMS, these data are made available by the Minnesota Population Center.[15] For most samples, NAPP generates family interrelationship linkages. However, in a few cases (Canada for 1871 and 1881 and Germany[16] in 1819) such linkages are not available. In those cases, we use similar rules developed to link mothers and children in the U.S. full count census. Also, consistent with the pre-1940 U.S. censuses, labor force activity is based on whether women report an occupation rather than the modern definition of working or seeking work within a specific reference period, and education is unavailable.[17]

Between the International IPUMS and the NAPP, we are able to build sporadic panels for four non-U.S. countries – Canada, the United Kingdom, France, and Ireland – observed at different stages of the development cycle. There are five Canadian censuses between 1871 and 2011, four British censuses between 1851 and 1991, eight Irish censuses between 1971 and 2011, and eight French censuses between 1962 and 2011.

d. Demographic and Health Surveys (DHS), 1990-2014

We supplement the censuses with the Demographic and Health Surveys (DHS).[18] From the initial set of 254 country-year surveys, spanning 6 waves from the mid-1980s onward, we exclude samples missing age of mother, marital status of mother, current work status, whether the mother works for cash, birth history, and comparable real GDP per capita. These restrictions force us to drop the first wave of the DHS, leaving 692,923 mothers in 192 country-years.

The DHS includes a number of questions that are especially valuable for testing the robustness of our census results. First, detailed health information allows us to control for characteristics that may be related to a mother's likelihood of twinning (Bhalotra and Clarke 2016). Second, we can use an indicator of whether children are in fact twins to test the accuracy of our coding of census twins.[19] To keep the DHS results comparable to the censuses, our

---

[15]See Minnesota Population Center (2015), North Atlantic Population Project: Complete Count Microdata, Version 2.2 [Machine-readable database], Minneapolis: Minnesota Population Center.

[16] The NAPP 1819 German data is from the small state of Mecklenburg-Schwerin, rather than the whole region of Germany. However, we refer to it as Germany for expositional purposes.

[17] In the NAPP, the occupation definitions are based on the variables *occgb*, *occhisco*, and *occ50us*. Note that the NAPP occupation classifications are different than those used in the U.S. censuses, with the exception of the occupational coding used for Canada in 1911.

[18] For additional information about the DHS files see ICF International (2015). The data is based on extracts from DHS Individual Recode files. See http://dhsprogram.com/Data/.

[19]Appendix Figure A1 illustrates the high degree of correspondence between twinning rates when we define twins using "real" multiple births and those imputed for children sharing the same birth-year. The DHS has a number of labor force variables but none that directly compare to those in the censuses. We chose to use an indicator of

baseline DHS estimates identify twins based on the census year-of-birth criterion and consider only living children who reside with the mother.

e. Real GDP per Capita

Real GDP per capita (in US$1990) is collected from the Maddison Project.[20] To reduce measurement error, we smooth each GDP series by a seven year moving average centered on the survey year. We are able to match 441 country-years to the Maddison data.[21] This leaves a total of 48,423,496 mothers aged 21 to 35 with at least two children in our baseline sample.

When we split the 1930 and 1940 full population U.S. censuses into the 48 states and DC, we bin those samples by state-specific 1929 or 1940 income-per-capita.[22] The income data are converted into 1990 dollars using the Consumer Price Index.

f. Summary Statistics

Table 1 provides summary statistics separately for the U.S. and non-U.S. samples and by real GDP per capita bins. Although the first bin (less than $2,500 GDP per capita) is dominated by DHS samples, most bins have a large number of mothers for both U.S. and non-U.S. samples. Appendix Table A1 provides additional descriptive statistics by individual country-year datasets.

V. Results

a. OLS Estimates

We begin with estimates from OLS regressions of the labor supply indicator on the indicator for a third child and the controls described above. These results do not have a clear causal interpretation, but they are useful for establishing key data patterns. In Figure 1, we plot the coefficients for the U.S., the non-U.S. countries, and the combined world sample (labeled "All"), binned into the seven ranges of real GDP per capita reported on the x-axis ($0-2,500, $2,500-5,000, etc.). Point estimates and country-year clustered standard errors are provided in Table 2. The three samples exhibit a similar pattern. At low levels of real GDP per capita, the

whether the mother is currently working since it is most correlated with the IPUMS labor force measures (see Appendix Figure A2).

[20] See http://www.ggdc.net/maddison/maddison-project/home.htm.

[21] In a few minor cases, we were not able to match a country to a specific year but still left the census in our sample because we did not believe it would have impacted their placement in a real GDP per capita bin. In particular, the censuses of Denmark in 1787 and 1801 are matched to real GDP per capita data for Denmark in 1820 and Norway in 1801 is matched to data for Norway in 1820. Excluding these country-years has no impact on our results. More importantly, the Maddison data ends in 2010 and therefore censuses or surveys thereafter are assigned their most recently available real GDP per capita data.

OLS estimate of the effect of children on mother's labor supply is negative and statistically significant at the 5 percent level but economically small in magnitude (e.g. -0.022 (0.005) in the lowest GDP bin). As real GDP per capita increases, the effect becomes more negative, ultimately flattening out between -0.15 and -0.25 beyond real GDP per capita of $15,000.[23]

Figure 2 plots the U.S.-only OLS results over time. [24] These estimates start out negative, albeit relatively small (e.g. -0.011 (0.004) in 1860 and -0.013 (0.0004) in 1910), decrease from 1910 to 1980, at which point the magnitude is -0.177 (0.001), and flattens thereafter.[25]

Figure 3 plots the OLS estimates by real GDP per capita separately by time periods (pre-1900, 1900-1949, 1950-1989, and 1990+). Years prior to 1950 combine U.S. census and NAPP data. Years thereafter include all four of our databases. The same general pattern appears *within* time periods.[26] The effect of fertility on labor supply tends to be small at low levels of GDP per capita but increases as GDP per capita rises.

b. Twins IV

The left panel of Figure 4 shows the first-stage effect, γ in equation (9), of a twin birth on our fertility measure, the probability of having three or more children. For the U.S., non-U.S., and combined world samples, there is a positive and concave pattern, with the first-stage increasing with higher real GDP per capita up to $15,000 or so and flattening thereafter. Note that the regression specification controls for the mother's age, but does not, indeed cannot, control for the number of children or target fertility. Therefore, the positive gradient over real GDP per capita reflects the negative impact of income on target fertility and hence the heightened impact of a twin birth on continued fertility relative to a non-twin birth.[27] In all cases, the instrument easily passes all standard statistical thresholds of first-stage relevance, including among countries with low real GDP per capita and high fertility rates.

The right panel of Figure 4 plots β, the instrumental variables effect of fertility on

[23] Appendix Figure A3 shows similar evidence for Canada, France, Ireland, and the U.K.
[24] Blue circles represent IPUMS samples and red diamonds represent full population counts.
[25] Note that due to the sample size, 95 percent confidence intervals are provided but not visible at the scale of the figure.
[26] Relative to Figure 1, we combined some real GDP per capita bins because of small sample sizes within these tight time windows.
[27] The first stage coefficient, γ, is E{z=1|S=1,w} – E{z=1|S=0,w}. Mechanically, E{z=1|S=1,w}=1 because of the definition of twins. This means that if, for example, γ=0.6, then E{z=1|S=0,w}=0.4, implying that 40 percent of mothers would have a third child if their second child is a singleton. The increasing coefficient over real GDP per capita means having a third child after a singleton second child is declining with development. The reversal of this pattern at real GDP per capita of $10-15,000 in the U.S. represents the Baby Boom.

mother's labor supply.[28] In the world sample, β is mostly statistically indistinguishable from zero among countries with real GDP per capita of $7,500 or less. Subsequently, β begins to decline and eventually flattens out between -0.05 and -0.10 at real GDP per capita of around $15,000 and higher.[29] The results for the U.S. and non-U.S. samples are similar in that there is a notable negative gradient with respect to real GDP per capita. For example, above $20,000, the U.S. estimate is -0.070 (0.008) while the non-U.S. estimate is -0.105 (0.003).

In Figure 5, we show the U.S. twin results by census decade. The pattern is broadly similar to the previous figure. The magnitude of the first stage is increasing over time, and the second-stage IV results exhibit a pronounced negative gradient, particularly post-WWII.[30] Figure 6 shows that the negative gradient appears in four other developed countries in which we have longer, albeit more sporadic, time-series. In three of those countries – Canada, U.K., and Ireland – we explicitly estimate a near zero β at a low-income period and an economically large and negative β in a high-income period in their history. Finally, the same pattern arises within time periods (Figure 7), datasets (Appendix Figure A4), and geographic regions of the world (Appendix Figure A5). We think it is particularly notable that the declining β appears prior to the wide-spread availability of modern fertility treatments like IVF in wealthy countries and after modern census questions on labor force participation and fertility were introduced in 1940. However, we have more to say about these potential concerns below.

c. Are There Positive Labor Supply Effects Among the Lowest Income Countries?

One surprising finding is that at low real GDP per capita levels, we sometimes estimate a positive labor supply response to childbearing. That is particularly evident in the pre-WWI U.S. estimates displayed in Figure 5, in addition to periodically positive but not statistically significant effects for some low-income, post-1990 countries.[31] The U.S. positive results are not statistically different from zero for the early census samples (1860, 1870), but they are for the

[28] The point estimates and standard errors from Figure 4 are also shown in Table 2.

[29] By comparison, Angrist and Evans (1998) report a twins IV estimate of -0.087 for the 1980 U.S. census.

[30] In our binned samples, we only include the U.S. full population for 1880 and 1910 to 1940. However, we display the single-year estimates from the IPUMS random samples for these years in Figures 2 and 5. We take the high degree of correspondence between the 1910 IPUMS and full population estimates as validation of our implementation of mother linkages.

[31] See Appendix Figures A5. On the regional figure, the estimates tend to be not statistically, nor economically, different from zero at low-income levels, with the exception of a single pooled sample from Asia, which is positive and significant. The Asian sample between $5,000-7,500 consists of 522,757 observations from 15 country-years. The pooled result for these 15 samples is almost completely driven by Turkey in 1990 and 2000, which have IV estimates of 0.200 (0.023) and 0.150 (0.017) and make up 163,770 and 180,069 observations, respectively.

full population counts of 1880 and 1910.

While these positive results are not artifacts in the statistical sense, it is worth noting that the underlying rates of labor force participation for U.S. women are very low at this time in history (e.g. 6.2 and 11.8 percent for 1880 and 1910 mothers, respectively). As such, a positive effect could reflect that low-income mothers are more likely to work after having children, for example because subsistence food and shelter are necessary, whereas childcare might be cheaply available. Section II discusses a simple extension to our theoretical model, the introduction of a consumption cost to children, which implies the potential for a positive labor supply response to additional children. Such a framework may be especially relevant for the subpopulation of compliers for the local average treatment effect – that is, mothers induced to have children who would not have otherwise.

To gain further insight into the low real GDP sample results, we split the U.S. 1930 and 1940 full population counts by state of residence and pool states into income-per-capita estimation bins (matching what we did with countries in previous figures). Figure 8 shows the now familiar upward sloping pattern to the first stage results by real income per capita. In the second stage, we see that the effect of fertility on labor supply is in general statistically indistinguishable from zero at low-income levels in 1930 and 1940 and overlaps with the low-income post-1990 non-U.S. results (shown in the green line). But we also find a small positive effect from the lowest income states in 1930, seemingly corroborating the positive estimates from a lower income U.S. prior to WWI.[32] These findings are directionally consistent with Godefroy (2017), who identifies a positive labor supply response to a legal intervention that increased fertility in modern Nigeria.

d. Same Gender IV

Next, we discuss results, displayed in Figure 9, that use the same gender instrument.[33] Like the twins IV, we estimate a positive gradient to the first stage with respect to real GDP per capita, although the interpretation of this pattern is different than for twins. In particular, the same-gender first-stage picks up the increased probability that a mother opts to have more than two children based on the gender mix of her children (rather than picking up the proportion of

[32] For the 1930 census, the states in that lowest bin ($2,000-3,000) are: Alabama, Arkansas, Georgia, Mississippi, North Carolina, North Dakota, New Mexico, South Carolina, and Tennessee.
[33] The point estimates and standard errors from Figure 9 are shown in Table 2.

mothers with incremental fertility when the twin instrument is zero, i.e., for non-twin births). Most importantly, we again see a negative gradient on the second stage IV estimates, from a close-to-zero effect among low GDP countries to a negative and statistically significant effect at higher real GDP per capita that flattens at around $15,000. Again, the negative estimates appear in the U.S. post-WWII (Appendix Figure A6). [34]

Our main intention is to highlight the similar shapes of the labor supply effect across the development cycle, despite using instruments that exploit difference sources of variation. Indeed, when we combine all possible instrument variation into a singled pooled estimator, as in Angrist, Lavy, and Schlosser (2010), our weighted average twin and same gender IV results also, unsurprisingly, shows the same strong negative gradient. That said, the magnitude of the same gender IV result is larger than the twin IV result at the high GDP per capita bins.[35] Since this is a local average treatment effect, this disparity suggests a greater effect of fertility on labor supply for those women induced to have an incremental child based either on son preference or the taste for a gender mix compared to those encouraged to higher fertility by a twin birth.

e. Hours

The results thus far are for the participation decision. Figure 10 plots twin IV results for the number of hours worked per week conditional on working. We include all country-years that contain a measure of hours worked, which unfortunately limits us to only 39 censuses.[36] Nevertheless, we again find no evidence of a labor supply response among mothers in low-income countries and a negative response of about 0.85 (0.28) hours per week among mothers in higher-income countries. As a benchmark, employed mothers work, on average, just under 33 hours per week in countries with real GDP per capita above $20,000, suggesting a roughly 2½ percent average decline in hours as a result of an additional child, conditional on working.

f. Robustness

This section describes a series of tests examining the consequence of omitted variables bias, alternative benchmarks of development, and a variety of data definition and sampling considerations.

[34] Like the twins estimates, we also find systematic evidence of a positive fertility-labor supply effect at low levels of income, which are statistically significant for the 1910, 1930, and 1940 U.S. censuses (see Appendix Figure A6).
[35] For example, at the $20,000 and above bin, the twin estimate is -0.070 (0.008) for the U.S. sample and -0.105 (0.003) for the non-U.S. sample. By comparison, the same gender estimates are -0.121 (0.008) for the U.S. sample and -0.173 (0.019) for the non-U.S. sample.
[36] We use eight U.S. censuses (1940-2010) and 31 International IPUMS censuses. The DHS and NAPP do not contain hours worked per week. When hours are reported as a range, we use the center of the interval.

f.1 Omitted Variables and Alternative Sources of Identification

Twin and same gender instruments are susceptible to omitted variables biases. These biases are likely to differ across instrument, suggesting that the twins and same gender IV estimates can be specification checks of each other (Angrist, Lavy, and Schlosser 2010). However, in this subsection, we push this idea further by providing three other sets of estimates that exploit alternative sources of instrument variation or control for observable characteristics that are known to explain variation in the treatment.

First, we examine a third instrument for fertility – the time that elapses between the parents' marriage and the couple's first birth ("time to first birth" or TFB) – introduced by Klemp and Weisdorf (2016). A long line of research in demography and medicine (Bongaarts 1975) uses birth spacing, not necessarily limited to first births, as an indicator of fecundity. While there is mixed evidence on the extent to which spacing is idiosyncratic (Feng and Quanhe 1996; Basso, Juul, and Olsen 2000; and Juul, Karmaus, and Olsen 1999), Klemp and Weisdorf argue that TFB is especially hard to predict based on observable characteristics outside of parent age and consequently is a valid indicator of ultimate family size. Because TFB requires marriage and birth dates, which are only available in the DHS, we cannot replicate the negative gradient across the development cycle. However, we do find that the TFB IV estimates are economically small and positive and statistically similar to twin IV and same gender estimates at the same low real GDP per capita level.[37]

Second, our baseline twin estimates condition on families with one child and compare those who then have a twin birth to those who have a singleton birth. Following Angrist, Lavy, and Schlosser (2010), we condition on different family size parities to capture variation from different sets of mothers. For example, one might expect that mothers with a large number of previous children would be less likely to adjust their labor supply in response to unexpected incremental fertility (for example, because of low incremental childcare costs for higher births). Indeed, as shown in Figure 11, we observe a stronger first stage effect for the sample that conditions on more children, especially at higher income levels. In the second stage, we see a notably, although not always statistically significantly, more negative effect in high-income

[37] The TFB IV estimates using the DHS data are: 0.031 (0.018), 0.047 (0.015), and 0.044 (0.014) for the $0-2,500, $2,500-5,000, and $5,000-10,000 GDP per capita bins, respectively. Unfortunately, our data does not allow us to systematically study other instruments used in the literature, such as the use of infertility treatments (Cristia 2008; Aguero and Marks 2011; Lundborg, Plug, and Rasmussen 2016), changes in access to birth control (Bailey 2013), or other policy changes (Bloom et al. 2009; Godefroy 2017).

countries for women starting with one child. However, the pattern of results is similar regardless of how many children are in the household when the twins are born. In all non-zero family size circumstances (up to three initial children), we continue to find no effect among low-income countries and an increasingly larger negative effect among higher income countries, flattening out around $20,000 per capita.[38]

Third, it has been noted by many researchers, most recently Bhalotra and Clarke (2016), that mothers of twins may be positively selected by health and wealth.[39] We provide two additional pieces of evidence that this selection process is not driving the negative labor supply gradient. When we control for the observable characteristics that have been highlighted by Bhalotra and Clarke (2016), such as mother's education, medical care availability, and mother's health, our results are statistically identical to the baseline estimates without these controls.[40] In addition, a strand of the medical literature argues that the proportion of dizygotic twins is affected by environmental and genetic factors of the type discussed by Bhalotra and Clarke (2016). By contrast, the proportion of monozygotic twins appears to be relatively constant over time and less affected by their omitted variables bias concern.[41] In Figure 12, we report that

[38] Additionally, we used a DHS question that elicits parent's ideal number of children. In particular, we restrict the sample to mothers whose ideal number of children are less than three (or four) and obtain nearly identical point estimates. This test loosely addresses concern that the parities we consider would not be binding and, consequently, have no labor supply effect in high-fertility, low-income countries.
Unfortunately, by construction, the twin, same gender, and time to first birth instruments are unable to identify the labor supply effect from an unexpected first child. The best causal evidence on the impact of first births uses childless mothers undergoing in vitro fertilization (IVF) treatments. Interestingly, Cristia (2008) and Lundborg, Plug, and Rasmussen (2016) find large negative labor supply responses to successful IVF treatment in the U.S. and Denmark, respectively. By contrast, Aguero and Marks (2008, 2011) find no impact among 32 developing countries. While, we cannot replicate these findings with our data, the patterns seem to further validate a negative labor supply gradient across all family parities.

[39] Related, Rosenzweig and Zhang (2009) argue twins are less costly to raise than two singleton births spaced apart. While we cannot fully address this concern, we can restrict the analysis to mothers with close birth-spacing. Appendix Figure A7 shows that this restriction has little impact on our results.

[40] Appendix Figure A8 plots the results with and without mother's education covariates using all available censuses and the DHS. Health measures are available only in the DHS. We are able to roughly replicate Bhalotra and Clarke's association between twinning and doctor availability, nurse availability, prenatal care availability, mother's height, mother's BMI (underweight and obese dummies), and infant mortality prior to birth. When we specifically control for these measures, our labor supply IV estimates are identical to the baseline for the <$2,500 bin and only slightly larger but statistically and economically indistinguishable for the $2,500-$5,000 bin (-0.006 (0.031) versus 0.012 (0.028)) and $5,000 and over bin (-0.075 (0.042) versus -0.043 (0.039)).

[41] We cannot identify monozygotic and dizygotic twins in our data but we can exploit the fact that monozygotic twins are always same gender, whereas dizygotic twins are an equal mix of same and opposite gender (like non-twin siblings). The rate of monozygotic twinning is approximately 4 per 1000 births and is constant across various subgroups (Hoekstra et al. 2007). Under the standard assumption that dizygotic twins have a 50 percent chance of being the same gender, approximately 43 to 59 percent of same-gender twins are monozygotic across the various GDP bins. Notably, the proportion of monozygotic twins will be highest in low-GDP countries, where Bhalotra and Clarke (2016) find the potential for the omitted variable bias is greatest.

results are statistically indistinguishable across same and opposite gender twins, lending additional credence to the view that our results are not driven by omitted variable bias with respect to twinning.

f.2 Alternative Development Benchmarks

The labor supply patterns we have documented thus far are based on an economy's real GDP per capita. The key model prediction, however, is based on the substitution and income effects arising from changes to a woman's wage. Unfortunately, data limitations make it difficult to show world results stratified by female (or overall) wages. However, for the 1940 to 2010 U.S. censuses, we can compute average female real wage rates by state and census year.[42] Results are presented in Figure 13, stratifying observations into four real hourly wage bins, ranging from under $6 to over $12 per hour, based on the average wage in the state at that time. Similar to the GDP per capita results, we find no labor supply effect at the lowest real wage levels and larger negative effects as the real hourly wage rises. Second, again for a subset of the sample, we can stratify by the average education level of women aged 21 to 35 (Figure 14).[43] We again find no effect at low education levels (below 9 years) but decreasing negative effects thereafter. Third, and perhaps more directly tied to Schultz (1991), we find the same pattern by agricultural output. In this case, the negative gradient begins when agricultural employment drops below 15 percent.

f.3 Data Issues

Several variable definition choices that we make in our baseline estimates could conceivably be problematic, including a) using calendar year to identify twins, b) using occupation to define LFP in historical censuses, and c) counting biological children. We discuss each of these issues in turn.

Since few censuses record multiple births or the birth month/quarter, out of necessity we label siblings born in the same year as twins. Naturally, this classification raises the risk that two

[42] There is no wage data prior to 1940. For all persons aged 18 to 64, we calculate the average hourly wage rate as annual earned income divided by weeks worked times hours worked per week. The age range overlaps with the cohort of mothers used in our baseline sample but we do not condition on gender or motherhood. The results are robust to using the average wage rate of men or women only as well. Wages are inflation adjusted using the consumer price index to 1990 dollars and winsorized at the 1st and 99th percentiles in each census prior to taking means.

[43] Again, data availability limits our analysis to 1940 and later. We also exclude 30 country-years where years of education are not provided. By 1940, U.S. women in their twenties and thirties had, on average, at least 9 years of education. Consequently, the U.S. is included only in the two highest education bins (9 to 12 and 12+ years).

births in the same calendar year could be successive rather than twins (so-called Irish twins). Fortunately, for a subset of our data, quarter or month of birth or direct measures of multiple births are available. Figure 15 presents results using both definitions of twins. By and large, we see a very similar negative gradient despite notably nosier estimates from a smaller sample of country-years with month or quarter of birth.[44]

Second, our historical results (1930 and earlier) use an occupation-based measure of labor force participation. Post-1940, we switch to the modern LFP definition based on whether the person is working or searching for work at the time of the survey. When both LFP measures are available, initially and most prominently in the 1940 U.S. census, changing LFP definitions has no impact on our results. Using the full population 1940 U.S. census, we find a 0.95 *cross-state* correlation between the two measures and a 0.82 *cross-state* correlation of the IV results (Appendix Figure A9). More generally, Figure 16 illustrates the same general pattern of results when using: a) an occupation-based LFP for all post-1940 censuses that contain occupation, b) an indicator of whether the mother is employed at the time of the census/survey or c) an indicator of whether the mother worked over the prior year.[45]

Despite the correspondence between the modern definition of LFP and the historical occupation-based results, there is still valid concern that specific women's occupations are misreported prior to 1940 and therefore could bias our results. In particular, Goldin (1990) highlights the mismeasurement of agricultural women workers in cotton growing states, an undercount of women in manufacturing, and mismeasurement of boardinghouse keepers. While it is not possible to directly address the issues raised by Goldin, Figure 17 presents pre-1940 results that individually and simultaneously adjust the sample for each of these groups.[46] Again, the findings are qualitatively similar to our baseline.

Another measurement concern relates to non-biological children and children who have

[44] By comparing the black and red lines which both use the year-of-birth twin definitions but run regressions on different samples, it appears that the low-income country-years with month and quarter of birth are biased away from zero whereas the opposite is the case for high-income countries. Nevertheless, the blue line (twins defined by month or quarter of birth) still exhibits a negative gradient.

[45] The baseline LFP, employment, and occupation-work results (black, blue, and red lines) use identical samples. The sample size for worked last year (green line) is roughly 1/9 as large as the other samples. Despite different sample composition, the worked last year results still correspond well with the results from other employment measures.

[46] That is, we exclude women in cotton growing states and who list their industry as manufacturing. As an upper bound for boardinghouse keeper employment, we recode women as employed if the household has any members who identify their relationship to the household head as a boarder.

left the household. Data identifying biological children are not consistently available across censuses. However, when we have information on the number of children to which a mother has given birth, we find that restricting our sample to mothers where this number matches the total number of children in the household has little impact on the results (see Figure 18). This restriction addresses concerns resulting from infant mortality, older children moving out the household, and complications resulting from step-children and children placed into foster care (Moehling 2002).

More broadly, we find it reassuring that the key pattern in the data is preserved when excluding the lower quality, pre-1940 data altogether. Namely, the female labor supply response to children in 1940 was economically small (Figures 5, 8, Appendix A6) and only gets significant post-1940. This pattern suggests that our main findings are not driven by inconsistent historical data and sampling. In addition, our various robustness checks suggest that data issues are not the reason for the relatively constant labor supply response to children in the half century or so leading up to WWII.

Finally, our findings are robust to a number of other reasonable tweaks to our specification, variable definitions, and sample selection, such as excluding country-year fixed effects and alternative ways to specify the mother's age and age at first birth covariates, as well as parsing the sample by age, age at first birth, education, and marital status of the mother. [47] Using the methods proposed by Angrist and Fernandez-Val (2010) and Bisbee et al. (2017) to reweight our IV estimates to a common complier population, namely the covariate distribution for compliers in the U.S. in 1980, also has no impact on the results (Appendix Figure A15).

VI. Channels

This section explores some of the potential mechanisms that account for the remarkably robust negative income gradient of mother's labor supply response to children.[48]

a. Accounting for Base Rates of Labor Force Participation

One possibility is that the negative gradient is simply a function of the base rate of labor force participation. With respect to our theoretical model, a lower base rate of labor force

[47] We find consistently larger negative effects among single (relative to married) and younger (relative to older) mothers, especially in countries with higher GDP per capita. However, those cases still exhibit the same negative gradient across development. Moreover, there is no statistical or economic difference across gender and mother's education at any level of GDP per capita. These figures can be found in Appendix Figures A10 to A14.

[48] As the main area of interest is the causal labor supply effect of children and the strength of the instruments are apparent, we stop reporting the first-stage estimates. For brevity, we concentrate solely on the second-stage twin estimates.

participation would imply more corner ($l = 0$) cases, for which there is no scope for a negative fertility effect on labor supply. This mechanically limits the scale of any average causal effect of fertility. We can account for this possibility by rescaling estimates to the relevant base rate. The rescaling relies on the assumption that effects tend to be monotonic in the population under study. That is, write the average effect in population *s* as,

(11) $$\beta_s = E_s[Y_1 - Y_0],$$

where Y_1 and Y_0 are potential labor outcomes (with support $\{0,1\}$) under the condition of three or more children and less than three children, respectively. Effect monotonicity implies $Y_1 \leq Y_0$, which also means

(12) $$E_s[Y_1 - Y_0 | Y_0 = 0] = 0.$$

This further implies that

(13) $$\beta_s = E_s[Y_1 - Y_0 | Y_0 = 1]\mathrm{E}_s[Y_0],$$

in which case the average effect of having three or more children *among those for which there can be an effect* is given by

(14) $$\beta_s^r = E_s[Y_1 - Y_0 | Y_0 = 1] = \frac{\beta_s}{\mathrm{E}_s[Y_0]}.$$

Comparing trends in β_s versus β_s^r allows us to assess the influence of base participation rates.[49]

Given that we are estimating complier LATEs via IV, the populations indexed by *s* correspond to the compliers in our various country years. As such, the relevant base rate, $E_s[Y_0]$, corresponds to the labor force participation rate among compliers with instrument values equal to 0. We compute these complier-specific rates using the IV approach of Angrist, Pathak, and Walters (2013).[50]

Figure 19 shows the rescaled baseline twins estimates. For the U.S., the rescaling results in a substantial flattening past $7,500 per capita. For the non-U.S. populations, the rescaled estimates are consistent (taking into account the uncertainty in the estimates) with a flattening after $10,000 per capita. However, a negative gradient is still evident over lower levels of

[49] This rescaling recovers a meaningful effect in populations for which the monotonicity assumption is reasonable. Rescaling would not be valid in country-years, such as those described in Section V.c, where we estimate statistically significant positive fertility effects. Our figures are based on samples that include positive estimates. If we apply our rescaling strategy to country-year samples for which we observe either negative or (statistically indistinguishable from) zero fertility effects, we still recover a comparable negative gradient, although, unsurprisingly, labor supply responses at all real GDP per capita levels become more negative.

[50] Specifically, we stack the two-stage estimation used in Angrist, Pathak, and Walters (2013) to calculate the complier-control mean with our baseline two-stage least squares regression to get the covariance between the base rate and the labor supply effect.

income. This indicates that the decline in the labor supply effect of an additional child is not solely driven by increases in the base rate of mother's LFP and motivates further analysis into the channel driving the negative gradient, particular over income levels under $10,000 per capita. The analyses below examine results both with and without the base-rate rescaling.

b. **Changes to the Income and Substitution Effect Across Stages of Development**

We believe much of the remaining negative gradient is due to a declining substitution effect, in combination with an unchanging income effect resulting from increasing wages for women during the process of economic development.

We identify the substitution effect primarily through changes in job opportunities. This exercise is motivated by previous work that documents a U-shape of female employment with development in the U.S. and across countries (Goldin 1995; Schultz 1991; Mammen and Paxson 2000). Schultz (1991) shows that the U-shape is not observed within sector. Rather, it is explained by changes in the sectoral composition of the female labor force. In particular, women are less likely to participate in unpaid family work (mostly in agriculture) and self-employment and more likely to be paid a wage in the formal sector in the later stages of the development process. In addition, we have reason to believe that the changes in the types of jobs that women have over time might become less compatible with raising children. For example, in rural, agricultural societies, women can work on family farms while simultaneously taking care of children, but the transition to formal urban wage employment is less compatible with providing care at home (Jaffe and Azumi 1960; McCabe and Rosenzweig 1976; Kupinsky 1977; Goldin 1995; Galor and Weil 1996; Edwards and Field-Hendrey 2002; and Szulga 2013).

Given that consistent information on occupations and sectors across our many samples is limited, we rely on two coarse indicators of job type that can be consistently measured in almost all of our data. First, we try to capture the distinction between urban/rural and formal/informal occupations by changing the outcome to be whether women work for a wage or work but are unpaid. These results, unscaled (left) and scaled (right), are presented in Figure 20. We find the changing relationship between fertility and labor supply is driven by women who work for wages. The response from women who are working but not for wages is small and statistically indistinguishable at different levels of real GDP per capita. Note again, that, since these are rescaled estimates, the gradient – or lack thereof – is driven not by changes in aggregate levels of labor force participation at different levels of GDP per capita, but by changes in the sectoral composition of the labor force.

A second proxy of sectoral shifts is whether women work in the agricultural or non-agricultural sectors (Figure 21). Although the scaled results presented in the right plot are unfortunately noisy for agricultural labor, the labor supply response of women in non-agricultural sectors becomes clearly more negative as real GDP per capita rises. We also observe in Figure 22 that fertility has almost no differential effect across the development cycle on female labor supply to professional occupations, despite the fact that these occupations tend to have higher wages.[51] Instead, the changing gradient seems to be driven entirely by women who work in non-professional occupations, suggesting either that education and professional status are poor proxies for the substitution effect or that the opportunity differences they capture are small in comparison to the sectoral shifts out of agricultural and non-wage work. [52,53]

By contrast, we believe the income effect of rising wages is likely small and invariant to the stage of development. We show this in two ways. First, we look at the husband's labor supply response to children using the same twin IV estimator. A long literature, tracing back to classic models of fertility such as Becker (1960) and Willis (1973), argues that an increase to the husband's wage increases the demand for having children, possibly because men spend less time rearing children. That is, the income effect is dominant. In Figure 23, we return to the unscaled estimates and show that the husband's labor supply response is economically indistinguishable from zero and invariant to the level of real GDP per capita. Second, we use the 1940 to 2010 U.S. censuses, which contain hourly wages of husbands, to measure the differential labor supply response of married women throughout the hourly wage distribution of their spouse. In Figure 24, mothers are stratified into three groups based their husband's real wage (under \$10, \$10-\$16

[51] Professional occupations are defined somewhat differently across data sources. For the U.S., we define professionals as Professional, Technical, or Managers/Officials/Proprietors. This definition corresponds to 1950 occupation codes 0-99 and 200-290. For IPUMS-I, we use the International Standard Classification of Occupations (ISCO) occupation codes. For the NAPP, we use the Historical ISCO codes, except for 1911 Canada where we use 1950 U.S. occupation codes. We dropped the 1851 and 1881 U.K censuses due to difficulty convincingly identifying professionals. For the DHS, we use their occupation codes. In all non-U.S. sources, we define professionals as close as possible to the U.S.

[52] The fertility response literature has long used a woman's education to proxy for the type of jobs and wages available to her. While Gronau (1986) documents several results finding education is correlated with a fertility response, this correlation appears to reverse once Angrist and Evans (1998) apply instrumental variables. We find no strong heterogeneity by education (Appendix Figure A13).

[53] Note that $\partial^2 l/\partial n \partial w$ becomes more negative as the level of the mother's wage declines. Thus the model predicts that the negative gradient will be sharper among lower-skilled women.

and above $16 measured in 1990 dollars).[54] Generally, we find no differential response, again suggesting that the income effect is unlikely to be a driver of the negative gradient in the labor supply response to children over the development cycle.

c. **Child Care Costs**

A key factor driving the relationship between mother's labor supply and children is the time cost of raising kids.[55] One simple indication that child care costs could be a relevant channel is visible in Figures 25 and 26, which stratify the samples by six year age bins of the oldest or youngest child respectively. Regardless of kids' ages, we find a negative gradient, with the labor supply elasticity declining at real GDP per capita around $7,000 - $15,000. However, the gradient is monotonically sharper for families with younger children who typically require more care, and especially among mothers in non-professional occupations with younger children (Table 3).[56] In particular, among mothers with a child under 6, the impact of a child on working in a non-professional occupation falls by -0.066 (0.010) in countries with real GDP per capita above $10,000 relative to countries below $10,000.[57] By comparison, the non-professional gradient falls to -0.054 (0.011) and -0.020 (0.021) for mothers with a youngest child between 6 to 11 and 12 to 17. Strikingly, the labor supply gradient among professional occupations is invariant to the age of the youngest child. These results are at least suggestive that non-professional mothers, who are most exposed to sectoral shifts over the development cycle, may also be least likely to be able to pay for childcare costs through formal wage work.

Ideally, we would test the importance of child care costs with convincing sources of exogenous variation across countries or over time. Unfortunately, we are not aware of such variation that spans our data. There is, however, a growing literature that uses quasi-experimental variation in access to child care or early education to study mother's labor supply in individual

---

[54] Figure 23 is an extension of Figure 13, where the states are grouped into bins by the average wage of all 18-64 year olds and mothers are separated within bins by their spouse's wage.

[55] Recall equation (7): $\frac{\partial l}{\partial n} = -\frac{\alpha^{\theta} b}{w^{\theta+1}\gamma^{\theta}+\alpha^{\theta}} < 0$ where b is the time cost of children.

[56] There is a monotonic relationship between age of children and time spent on child care. For example, in the U.S. Time Use Survey, 21-35 year old women with two children at home where one was under 6 spent 2.9 hours per day, on average, on child care (plus an additional 2.5 hours per day on other household activities). By comparison, when the youngest child is 6 to 11 or 12 to 17, mothers spend 1.8 and 1.3 hours per day, respectively, on child care. For the subset of mothers who are not working, child care takes up 6.8 (youngest child under 6), 5.4 (6 to 11), and 4.7 (12 to 17) hours per day.

[57] For exposition and due to sample size concerns that arise when dividing samples too finely, country-years in Table 3 are sorted into two real GDP per capita bins: above and below $10,000. The bottom row, labeled "gradient," is the difference.

countries, including the U.S. (Cascio 2009; Fitzpatrick 2012; Herbst 2017), Argentina (Berlinski and Galiani 2007), Canada (Baker, Gruber, and Milligan 2008), and Norway (Havnes and Mogstad 2011).[58] Summarizing this literature, Morrisey (2017) concludes that the availability of child care and early education generally increases the labor supply of mothers, although there is some response heterogeneity across countries. We view this literature as at least consistent with the possibility that the negative labor supply gradient may be amplified if child care costs increase because jobs become less conducive to child rearing, and, if so, this dynamic could be stronger among lower wage mothers with less flexibility to provide child care to young children (Blau and Winkler 2017).[59]

d. **Access to Oral Contraceptives**

Lastly, the evidence from countries for which we have data spanning the development cycle (see Figures 5 and 6) show that mothers' labor supply response to children likely falls in the decades immediately after WWII, a period in which birth control pills were introduced and widely dispersed in the developed world. To test whether our results are possibly related to this new development, we examine differences in the timing in which U.S. states allow access to birth control pills among 18 to 21 year olds (Bailey et. al. 2012). Using mothers in the 1970 and 1980 censuses and a difference-in-difference design, we find no evidence that access to birth control impacted the labor supply decisions of mothers in response to unexpected births. Combined with a robust cross-sectional negative mother labor supply gradient over the last couple of decades, when much of the world has access to oral contraceptives, we do not see compelling evidence that changing access to birth control is likely an important explanation of our main findings.

[58] To take one example, Herbst (2017) is based on the WWII-era U.S. Lanham Act that provided childcare services to working mothers with children under 12. State variation of funding offered a natural experiment in a period when we find the aggregate labor supply response of mothers to additional children was close to 0. Herbst reports that additional Lantham Act child care funding raised mother's labor force participation.

[59] We have examined non-exogenous sources of variation in childcare costs by splitting country-years by the propensity at the national level of households to have access to multigenerational living arrangements or pre-school attendance, sources of childcare that vary across the development cycle (see Ruggles 1994 on multigenerational families). We compute the share of households in multigenerational living arrangements using our census data and use pre-school attendance data collected by the World Bank. We find no evidence that either impacts mothers' labor supply decisions. Without a fuller model that allows us to understand the sources of variation in multigenerational families and pre-schools, these results are inconclusive. Nevertheless, they highlight appropriate caution in over-interpreting the role that child care costs may play in explaining the negative labor supply gradient.

VII. Conclusion

In her classic monograph of the evolution of women's work in the United States, Goldin (1995) documents a U-shaped evolution of women's labor supply over the 20th century. At the same time, she notes the paucity of historical causal evidence on the link between fertility and labor supply. A parallel literature in development economics has investigated the implications of evolving patterns of fertility in developing countries on economic growth (and implicitly labor supply). While there have been many notable and pioneering studies on the effect of fertility on labor supply in developing countries, they naturally tend to focus on single countries or non-causal evidence.

Using a twin birth and same gender of the first two children as instruments for incremental fertility, this paper links these two literatures by examining causal evidence on an evolution of the response of labor supply to additional children across a wide swath of countries in the world and over 200 years of history. Our paper has two robust findings. First, the effect of fertility on labor supply is small, indeed typically indistinguishable from zero, at low levels of income and both negative and substantially larger at higher levels of income. Second, the magnitude of these effects is remarkably consistent across the contemporary cross-section of countries and the historical time series of individual countries, as well as across demographic and education groups.

Our results are consistent with a standard labor-leisure model. As income increases, individuals face an increased time cost of looking after children but also experience higher incomes. The former dominates the latter. This substitution effect seems to arise from changes in the sectoral and occupational structure of female jobs, in particular the rise of non-professional, non-agricultural wage work that flourishes with development. We also show that the negative gradient is steeper among mothers with young children that work in non-professional occupations and argue that access to child care subsidies may attenuate the negative gradient, suggesting that the affordability of child care costs may play a key role in declining LFP during the development cycle.

In discussing the evolution of female labor force participation in the United States, Goldin (1990) notes that "… women on farms and in cities were active participants [in labor] when the home and workplace were unified, and their participation likely declined as the marketplace widened and the specialization of tasks was enlarged." In examining the relationship between labor supply and fertility over the process of development, we arrive at a parallel conclusion. The declining female labor supply response to fertility is especially strong in wage work that is likely the least compatible with concurrent childcare.

We see three implications of our results. First, in thinking about the U-shaped pattern of labor force participation that has been widely document in the economic history literature, our results suggest that decreases in fertility play an explanatory role. That is, as fertility rates have declined over the latter half of the 20^{th} century, the responsiveness of labor supply to fertility has increased, contributing to increases in female labor force participation. Second, among developing countries, our results however suggest that changes in fertility tend not to have a large impact on labor force participation, arguing against fertility-reduction policies specifically motivated by women's labor force participation and its contribution to growth. Third, at least when it comes to fertility and labor supply, our results point to a remarkable consilience between historical and contemporary developing country data, suggesting that each of these disciplines has important insights for the other.

Working Paper Series

A series of research studies on regional economic issues relating to the Seventh Federal Reserve District, and on financial and economic topics.

The Effects of the Massachusetts Health Reform on Financial Distress **WP-14-01**
Bhashkar Mazumder and Sarah Miller

Can Intangible Capital Explain Cyclical Movements in the Labor Wedge? **WP-14-02**
François Gourio and Leena Rudanko

Early Public Banks **WP-14-03**
William Roberds and François R. Velde

Mandatory Disclosure and Financial Contagion **WP-14-04**
Fernando Alvarez and Gadi Barlevy

The Stock of External Sovereign Debt: Can We Take the Data at 'Face Value'? **WP-14-05**
Daniel A. Dias, Christine Richmond, and Mark L. J. Wright

Interpreting the *Pari Passu* Clause in Sovereign Bond Contracts:
It's All Hebrew (and Aramaic) to Me **WP-14-06**
Mark L. J. Wright

AIG in Hindsight **WP-14-07**
Robert McDonald and Anna Paulson

On the Structural Interpretation of the Smets-Wouters "Risk Premium" Shock **WP-14-08**
Jonas D.M. Fisher

Human Capital Risk, Contract Enforcement, and the Macroeconomy **WP-14-09**
Tom Krebs, Moritz Kuhn, and Mark L. J. Wright

Adverse Selection, Risk Sharing and Business Cycles **WP-14-10**
Marcelo Veracierto

Core and 'Crust': Consumer Prices and the Term Structure of Interest Rates **WP-14-11**
Andrea Ajello, Luca Benzoni, and Olena Chyruk

The Evolution of Comparative Advantage: Measurement and Implications **WP-14-12**
Andrei A. Levchenko and Jing Zhang

Saving Europe?: The Unpleasant Arithmetic of Fiscal Austerity in Integrated Economies **WP-14-13**
Enrique G. Mendoza, Linda L. Tesar, and Jing Zhang

Liquidity Traps and Monetary Policy: Managing a Credit Crunch **WP-14-14**
Francisco Buera and Juan Pablo Nicolini

Working Paper Series *(continued)*

Working Paper Series *(continued)*

Working Paper Series *(continued)*

Insurance in Human Capital Models with Limited Enforcement **WP-16-08**
Tom Krebs, Moritz Kuhn, and Mark Wright

Accounting for Central Neighborhood Change, 1980-2010 **WP-16-09**
Nathaniel Baum-Snow and Daniel Hartley

The Effect of the Patient Protection and Affordable Care Act Medicaid Expansions on Financial Wellbeing **WP-16-10**
Luojia Hu, Robert Kaestner, Bhashkar Mazumder, Sarah Miller, and Ashley Wong

The Interplay Between Financial Conditions and Monetary Policy Shock **WP-16-11**
Marco Bassetto, Luca Benzoni, and Trevor Serrao

Tax Credits and the Debt Position of US Households **WP-16-12**
Leslie McGranahan

The Global Diffusion of Ideas **WP-16-13**
Francisco J. Buera and Ezra Oberfield

Signaling Effects of Monetary Policy **WP-16-14**
Leonardo Melosi

Constrained Discretion and Central Bank Transparency **WP-16-15**
Francesco Bianchi and Leonardo Melosi

Escaping the Great Recession **WP-16-16**
Francesco Bianchi and Leonardo Melosi

The Role of Selective High Schools in Equalizing Educational Outcomes: Heterogeneous Effects by Neighborhood Socioeconomic Status **WP-16-17**
Lisa Barrow, Lauren Sartain, and Marisa de la Torre

Monetary Policy and Durable Goods **WP-16-18**
Robert B. Barsky, Christoph E. Boehm, Christopher L. House, and Miles S. Kimball

Interest Rates or Haircuts?
Prices Versus Quantities in the Market for Collateralized Risky Loans **WP-16-19**
Robert Barsky, Theodore Bogusz, and Matthew Easton

Evidence on the within-industry agglomeration of R&D, production, and administrative occupations **WP-16-20**
Benjamin Goldman, Thomas Klier, and Thomas Walstrum

Expectation and Duration at the Effective Lower Bound **WP-16-21**
Thomas B. King

Working Paper Series *(continued)*

Working Paper Series *(continued)*

The Effect of Fertility on Mothers' Labor Supply over the Last Two Centuries **WP-17-14**
Daniel Aaronson, Rajeev Dehejia, Andrew Jordan, Cristian Pop-Eleches, Cyrus Samii, and Karl Schulze
