Tracking U.S. Consumers in Real Time with a New Weekly Index of Retail Trade

Scott A. Brave, Michael Fogarty, Daniel Aaronson, Ezra Karger, Spencer Krane
Federal Reserve Bank of Chicago
March 30, 2021

Abstract

We create a new weekly index of retail trade that accurately predicts the U.S. Census Bureau’s Monthly Retail Trade Survey (MRTS). The index’s weekly frequency provides an early snapshot of the MRTS and allows for a more granular analysis of the aggregate consumer response to fast-moving events such as the Covid-19 pandemic. To construct the index, we extract the co-movement in weekly data series capturing credit and debit card transactions, small business revenue, mobility, and consumer sentiment. To ensure that the index is representative of aggregate retail spending, we implement a novel benchmarking method that uses a mixed-frequency dynamic factor model to constrain the weekly index to match the monthly MRTS. We use the index to document several interesting features of U.S. retail sales during the Covid-19 pandemic, many of which are not visible in the MRTS. In addition, we show that our index would have more accurately predicted the MRTS in real time during the pandemic when compared to either consensus forecasts available at the time, monthly autoregressive models, or other high-frequency data that attempts to track consumer spending. The gains are substantial, with roughly 60 to 80 percent reductions in mean absolute forecast errors.

Keywords: mixed-frequency dynamic factor model, retail sales, consumer spending

1 Introduction

With the onset of the Covid-19 pandemic, many researchers turned to new high-frequency data sources to measure the impact of the virus on the U.S. economy. These alternative data sources provided private sector analysts and policymakers with valuable real-time information about the effect of the spread of Covid-19 on economic activity. Researchers also used these data to evaluate the impacts of federal, state, and local policies on households and businesses.

Though useful, these data are not typically derived from samples designed to be representative of the population at large. Notably, credit and debit card transactions or business electronic payments reflect the subset of consumers or businesses that use the particular service gathering the data. Accordingly, it can be problematic to draw inferences about aggregate economic conditions from these non-representative high-frequency time series.

This paper addresses these concerns in the context of high-frequency indicators of U.S. retail sales. We create a new weekly index that accurately predicts the U.S. Census Bureau’s Monthly Retail Trade Survey (MRTS), a carefully designed representative-sample survey that produces the gold standard measure of aggregate U.S. retail spending. The MRTS is released monthly with about a two-week lag. In contrast, our index can be produced weekly, providing an early snapshot of consumer activity. Moreover, the weekly frequency of our index allows for a more granular analysis than can be performed with monthly data of fast-moving changes in consumer behavior such as the stockpiling of goods immediately preceding the nationwide shutdowns in mid-March 2020 and consumer responses to the Covid-relief package stimulus payments.

Our index uses alternative data from a number of private vendors: store revenue data

---

1 See, for example, the case studies in [Brave et al. (2020)](#). Other researchers have used carefully designed surveys to produce more representative samples but at the cost of a lower frequency of observation, e.g. [Coibion et al. (2020)](#), [Bartik et al. (2020)](#), and the U.S. Census Bureau Household and Small Business Pulse surveys described at [https://www.census.gov/newsroom/press-kits/2020/pulse-surveys.html](#).

2 For example, the March 2020 MRTS was released on April 15, 2020. This means that researchers and policymakers had to wait over a month before understanding how the onset of Covid-19 in early March 2020 affected aggregate consumer spending.
from Womply; financial transactions from Facteus and Consumer Edge; consumer sentiment from Morning Consult; and retail foot traffic from SafeGraph; as well as more traditional publicly available data on motor fuel consumption from the U.S. Energy Information Administration (EIA). We construct the index using a mixed-frequency dynamic factor model that extracts the co-movement in these six weekly series and monthly retail and food services sales excluding automotive spending from the MRTS.\(^3\) The model constrains the latent factor in a way that ensures that growth in the resulting Weekly Index of Retail Trade matches the MRTS data at a monthly frequency.

We first use our weekly index to document several interesting features of U.S. consumer spending during the Covid-19 pandemic, many of which are not visible in the MRTS:

• Retail sales in the U.S. plummeted at the same time as the rapid increase in Covid-19 cases and the closure of nonessential businesses in mid-to-late March 2020; they then began to recover by mid-April 2020. There was also a “stockpiling” effect, where retail sales increased substantially in the weeks leading up to the large declines in March. These intra-month patterns are not apparent in the lower frequency MRTS.

• As state and local governments lifted stay-at-home orders and the federal government disbursed the first round of economic impact payments, the pace of recovery accelerated in April-June. However, progress over the summer of 2020 was uneven, with the variation in weekly sales coinciding with developments during the second wave of Covid-19 cases.

• Sales fell again in the fourth quarter of 2020 as the third wave of the virus hit but began to recover in late December and early January, with the weekly pattern pointing to the second round of economic impact payments playing an important role in boosting spending.

We use the weekly index to “nowcast” the MRTS in real time.\(^4\) Based on out-of-sample monthly predictions, we show that our index more accurately predicted retail and food services sales ex. autos from the MRTS during the March 2020–February 2021 period than either the consensus forecasts available at the time or monthly autoregressive models. The

\(^3\)We exclude automotive spending since consumer analysts often rely on MRTS excluding automotive spending for analyses while separately analyzing the automobile sector using industry reports on vehicle sales.

\(^4\)Our use of the word “nowcast” parallels that of Giannone et al. (2008) in referring to the contemporaneous forecasting of a macroeconomic time series that is published infrequently using information that is available in real time.
gains are substantial, with approximately 60 to 80 percent reductions in mean absolute forecast error.

Our results contribute to several related literatures. A number of recent papers have used credit and debit card transactions data as an alternative high-frequency source to track consumer spending (e.g., Aladangady et al. (2019), Dunn et al. (2020), Chetty et al. (2020), and Carvalho et al. (2020)). Similarly, researchers have used cellphone mobility measures (e.g., Atkinson et al. (2020) and Alexander and Karger (2020)) and daily consumer sentiment to track consumer behavior during the Covid-19 pandemic. However, to the best of our knowledge, we are the first to combine this information into a single measure in a way that retains comparability to the U.S. Census Bureau’s MRTS data. We show that by using multiple sources of data we more accurately track the underlying trend in aggregate retail activity relative to any individual data series including those used by the BEA and Chetty et al. (2020) to track consumer spending.

Other work has used similar high-frequency data in forecasting exercises. For example, Galbraith and Tkacz (2018) use monthly payments system data to nowcast Canadian retail sales and Gross Domestic Product (GDP), and Lewis et al. (2020) use a variety of weekly data to nowcast U.S. GDP. Our work differs in that we combine the weekly frequency of our data with a multivariate and mixed-frequency data structure akin to the dynamic factor models of Giannone et al. (2008) and Aruoba et al. (2009). Furthermore, we modify a traditional mixed-frequency dynamic factor model to exploit the representative sampling of the MRTS in a way that is similar to what Aruoba et al. (2016) do for U.S. GDP.

2 High-Frequency Data Sources

Our Weekly Index of Retail Trade is targeted to match retail and food services sales excluding automotive spending (ex. autos) from the U.S. Census Bureau’s Monthly Retail Trade Survey

5Ludvigson (2004) and Croushore (2005) also use consumer confidence data to forecast consumer spending. Unlike our high-frequency data results, they find little evidence that more traditional measures of consumer confidence are useful in predicting current growth in aggregate consumer spending.
The MRTS is based on a mailed survey of about 13,000 retail businesses that sell merchandise and related services to final customers. The data record sales over the entire month and are published with about a two week lag. Sales include both online and in-store purchases.

The MRTS is a vital snapshot of consumer spending. As the Census Bureau notes: “These data are widely used throughout government, academic, and business communities. The Bureau of Economic Analysis uses the estimates to calculate Gross Domestic Product. The Bureau of Labor Statistics uses the estimates to develop consumer price indexes and productivity measurements. The Council of Economic Advisers uses the estimates to analyze current economic activity. The Federal Reserve Board uses the estimates to assess recent trends in consumer purchases. The media use the estimates to report news of recent consumer activity. Financial and investment companies use the estimates to measure recent economic trends.”

To construct our weekly index, we complement the low-frequency MRTS data with several high-frequency measures of retail activity that inform the index’s within-month dynamics:

- Revenues for more than 400 thousand small businesses, from Womply;
- Credit and debit card transactions from a sample of over 30 million unique cards, collected by Consumer Edge;
- Transactions from a collection of over 90 million debit, general purpose, payroll, government cards, and single-issue gift cards from Facteus;
- Consumer sentiment from daily polls, conducted by Morning Consult;
- Retail foot traffic based on cell phone data, collected by SafeGraph; and
- Finished motor gasoline product supplied, from the U.S. Energy Information Administration.

---

6The sample of firms is chosen approximately every five years (most recently in 2018) and is then updated quarterly to reflect business “births” and “deaths.” Added firms are typically represented in the sample with a nine month delay. Estimates are updated annually when the MRTS is benchmarked to the Annual Retail Trade Survey.

7See https://www.census.gov/retail/mrts/aboutthesurveys.html. Wilcox (1992) describes the process by which the Bureau of Economic Analysis uses the MRTS.
2.1 Revenue and Transactions Data

Although they are correlated, the Womply, Consumer Edge, and Facteus datasets cover different scopes of businesses, consumers, and transactions, and hence each independently provides useful information for our index. To align ourselves as much as possible with the MRTS, we only use data for firms that are classified with either North American Industry Classification System (NAICS) codes or Merchant Category Codes (MCC) that are included in the retail and food services ex. autos aggregate sales measure.\footnote{NAICS codes are available for Consumer Edge. Facteus and Womply are instead categorized by MCC, which allows us to exclude transactions categorized as automotive.}

Turning to the specifics of each data source:

- The Womply data are from payment processors used by more than 400,000 primarily brick and mortar establishments in the United States.\footnote{Chetty et al. (2020) and Alexander and Karger (2020) also use the Womply data in their analysis of the pandemic’s effects on economic activity.} At about $400 billion, annual sales at Womply firms amount to a little less than 10% of our MRTS benchmark. Womply filters the data by removing businesses that are inactive or that exceed the Small Business Administration’s size threshold.\footnote{See https://www.sba.gov/document/support/OT1\_textendash\_table\_size\_standards for the definition of small business thresholds by industry.} Data are available at a daily frequency with a five- to seven-day lag.

- Consumer Edge tracks consumer spending from more than 30 million unique credit and debit cards. We use a version of the data in which the number of active cards is scaled to be consistent over time; this means that changes in spending will reflect changes in either the number of transactions per card or the size of transactions rather than the size of the underlying sample. The data capture about $60-65 billion in annual sales, or about 1.3% of our MRTS benchmark. Data are available at a daily frequency with a five- to seven-day lag.\footnote{Consumer Edge is geared toward providing real-time data for investors. For more information, see https://www.consumer-edge.com/}

- Facteus aggregates, anonymizes, and standardizes transaction-level data from a dozen banks, covering a total of more than 90 million debit cards, payroll cards, government benefit cards, and single-issue gift cards. The subset of Facteus transactions that we use amounts to about 1.25% of our MRTS benchmark.\footnote{Facteus’ share of retail and food services sales ex. autos increased to over 2% in the first four to five months after the onset of the pandemic. We view this as consistent with the stabilization of lower-income households’ spending by various income support policies, including extended unemployment insurance benefits, the Pandemic Unemployment Assistance program, and the $1200 economic impact payments that were all part of the CARES Act passed in March. For more evidence on the impact of the stimulus payments on spending behavior using the Facteus microdata, see Karger and Rajan (2020).} The data are available at a
daily frequency with a five- to seven-day lag.

Two issues suggest that a simple aggregation of these data would have difficulty matching the MRTS. First, sampling error could be large as, even together, the samples represent a small fraction of the spending covered by the MRTS. Second, and likely more important, systematic errors could arise because the alternative data reflect nonrandom slices of the MRTS universe.

The MRTS’s sample design and construction methodology are aimed at producing a representative sample of all U.S. retail and food services spending. In contrast, each of our alternative data providers record spending by whomever is covered by their service. For example, Womply measures activity only at small businesses, the Facteus data are weighted towards lower-income and younger consumers, and by construction, none of these data sources capture cash payments. These discrepancies cannot be eliminated by reweighting the alternative data using the same type-of-store weights that the Census Bureau uses, as these selection issues occur for every type-of-store category.

Instead, we construct a statistical index that treats the individual alternative data as “noisy” high-frequency measures of broader spending to isolate the common factor across datasets that is correlated with the MRTS. In this framework, the estimated factor loadings on the component series will capture systematic differences between the spending covered by the component sample and the MRTS universe, while the error term will reflect any remaining random variation idiosyncratic to each data source.

2.2 Consumer Sentiment, Mobility, and Gasoline Data

To aid in identifying the common factor, our model includes two non-spending series that have also been widely used to examine the impact of the pandemic on economic activity – consumer sentiment from Morning Consult and retail foot traffic from SafeGraph.\(^{13}\) – as

\(^{13}\)See, for example, the Mobility and Engagement Index described in Atkinson et al. (2020) produced by the Federal Reserve Bank of Dallas that is based on the SafeGraph data.
well as a publicly available weekly indicator of gasoline consumption from the U.S. Energy Information Administration (EIA). These three additional measures help align our high-frequency transaction data with the MRTS universe by capturing drivers of spending related to a broad base of U.S. households.

Morning Consult constructs consumer sentiment indices based on a nationally representative daily email survey of about 6,000 people across the United States. Their survey is based on five questions that are identical to those used in the monthly University of Michigan Survey of Consumers and is available daily, without a lag. It thus brings sample design discipline and timely information on household conditions to our index. We use weekly averages of their overall index of consumer sentiment.

SafeGraph uses cell phone data to measure visits to individual business establishments. They record NAICS code identifiers for these locations, which allows us to measure total visits (or foot traffic) to establishments defined to be in the MRTS universe. Since cell phone usage is ubiquitous, this measure may provide a fairly representative measure of the population’s visits to retail establishments. They also then would help capture retail sales that are not covered by credit and debit card transactions, such as payments with cash or check. They would not, however, capture online sales, which are included in the MRTS.

We also use EIA’s weekly data for finished motor gasoline supplied in our index. These data serve two purposes. First, they complement the SafeGraph data in capturing broad-based mobility. Second, the EIA data provide useful forecasting power for gasoline sales, which are a large and volatile component of the MRTS series.

---

14 For additional details, see https://morningconsult.com/2020/03/10/morning-consult-economic-intelligence-methodology/. More information on the University of Michigan Survey of Consumers can be found at https://data.sca.isr.umich.edu/.

15 Over 99% of establishments in the SafeGraph data are categorized at the 4-digit NAICS code level. A summary of the foot traffic data available from SafeGraph can be found at https://www.safegraph.com/data-examples/covid19-commerce-patterns.

16 These data are measured in thousands of barrels per day and represent shipments from “primary” supply chain facilities (refineries, bulk storage terminals, etc.) to retail outlets and other secondary suppliers. They thus differ from retail sales of gasoline by changes in inventories at retail gasoline stations and the shipment to the other secondary suppliers. These are generally small—indeed, the Bureau of Economic Analysis (BEA) uses these data to help estimate personal consumption expenditures of gasoline in the national accounts.
Figure 1 shows the six high-frequency time series in our seasonally adjusted Weekly Index of Retail Trade from January 2018-February 2021. The figure makes clear the extent of heterogeneity across data sources, even during the onset of the recession in March 2020. Our index aims to combine these different sources in a representative way to explain national retail activity at a weekly frequency.

3 Modeling Weekly Retail Sales

The statistical framework underlying our Weekly Index of Retail Trade is a mixed-frequency dynamic factor model with one latent factor. However, unlike a standard dynamic factor model, we impose an additional constraint that forces the latent factor to temporally aggregate to match the MRTS’s monthly retail and food services sales excluding autos data. Below, we describe the model and its estimation.

3.1 Establishing a Regular Weekly Calendar

Weekly data pose a particular problem for mixed-frequency models. With standard methods of defining the calendar, some weeks span two months, which is problematic for temporally aggregating a weekly sales measure to a month. Accordingly, we instead define an alternative calendar. To begin, we partition each month into four weeks in the following way: each of the first three seven-day periods within the month are categorized as a week and the remaining seven to ten days are grouped into the fourth week of the month. This process results in a regular calendar in which each week is identified with a unique month.

Within each of our weeks, we aggregate the daily high-frequency data by summing across

---

17 Several of these time series exhibit significant seasonal components that have been removed in the figure using the methodology described in the Appendix.

18 For additional information on dynamic factor models, see Stock and Watson (2011). Similar mixed-frequency models to ours include Aruoba et al. (2009) and Mariano and Murasawa (2003), who both estimate a latent factor describing changes in U.S. economic activity, as well as Brave and Butters (2012), who estimate a latent factor capturing U.S. financial conditions.

19 Three common standards for defining weeks are: the number of seven-day periods from the first day of the year; a consistent Monday starting day; or a Sunday start day.
the days within the week for the transaction data and by averaging across the days of the week for the consumer sentiment data. For the retail foot traffic and motor fuel data, which are reported in calendar weeks, we take weeks that span two months and allocate the visits or fuel supplied to each of the two months proportionally based on the number of days the week has in each month. We then re-allocate visits or fuel supply within the month to match the number of days in each of our four weeks.

Because the MRTS data are seasonally adjusted, we also seasonally adjust our weekly inputs before estimating our factor model. This seasonal pre-filtering turned out to be critical in extracting the signal from the volatile unadjusted input data. Our adjustment methodology accounts for the regular intra-month patterns in the data and the fact that the fourth week of each month contains a varying number of days. The full seasonal adjustment procedure is described in detail in the Appendix.

3.2 Benchmarking to the MRTS

In our framework, growth in the weekly data \( (W_{n,i,t}) \) are “noisy” measures of growth (in log differences) in latent weekly MRTS spending \( (F_{i,t}) \), with \( n \) denoting the indicator series and \( i \) the week of month \( t \). Each series loads onto the latent factor according to loadings \( \gamma_n \) with average growth rates \( \alpha_n \) and measurement errors \( \epsilon_{n,i,t} \) that follow first-order autoregressive processes. In terms of equations, with \( L \) being a weekly lag operator, we have

\[
W_{n,i,t} = \alpha_n + \gamma_n F_{i,t} + \epsilon_{n,i,t} \\
(1 - \psi_1 L) \epsilon_{n,i,t} = \nu_{n,i,t}.
\]

The factor follows a fourth-order autoregressive process with average growth rate \( \alpha_F \),

\[20\text{The Morning Consult data are a 5-day moving average. We back out daily values from the moving average and then re-average them to our weekly values. For details, see https://stats.stackexchange.com/questions/67907/extract-data-points-from-moving-average.}\]
\[(1 - \rho_1 L - \rho_2 L - \rho_3 L - \rho_4 L) F_{i,t} = \alpha_F + \eta_{i,t}.\]  

(3)

The shocks \(v_{n,i,t}\) and \(\eta_{i,t}\) are assumed to be jointly distributed \(N(0, \Sigma)\).

To maintain the link with the MRTS data, the factor’s weekly growth rates, \(M_{i=4,t}\), are constrained by the triangle average formula shown below,

\[M_{i=4,t} = \frac{1}{4} F_{i=4,t} + \frac{2}{4} F_{i=3,t} + \frac{3}{4} F_{i=2,t}\]
\[+ F_{i=1,t}\]
\[+ \frac{3}{4} F_{i=4,t-1} + \frac{2}{4} F_{i=3,t-1} + \frac{1}{4} F_{i=2,t-1}.\]

(4)

This temporal aggregation constraint ensures that the \(F_{i,t}\) generate a monthly series with the same growth rate as the MRTS data for retail and food services sales ex. auto.

To implement the triangle average, we assume that the log difference in monthly MRTS sales, \(M_{i=4,t}\), is observed in the fourth week of the month. In calendar time, this occurs near the middle of the following month with the release of the Advance Monthly Retail Trade Survey, or MARTS. The above mixed-frequency dynamic factor model is then put into state-space form using the Harvey (1990) accumulator to handle the temporal aggregation constraint imposed on the latent factor. We estimate the model by maximum likelihood using a Kalman filter\(^{21}\)

Unlike a standard mixed-frequency dynamic factor model, we do not include a measurement error term for the MRTS data. By treating them as being measured without error, we are in essence recursively benchmarking the latent factor to the representative MRTS data. However, this also means that the model would be over-identified if we make the typical

\(^{21}\)We use the Matlab toolbox MFSS described in Brave et al. (2020) for this purpose, where we further restrict \(\rho(L)\) and \(\psi_i L\) to be stationary processes.
assumption that $\Sigma$ is a diagonal variance-covariance matrix. Instead, we estimate the elements of $\Sigma$ associated with the covariances between $\eta_{i,t}$ and each of the $\nu_{n,i,t}$\footnote{This slight modification leads to an exactly identified model as well as modest gains in our ability to nowcast the MRTS data. This is because the additional covariances contain useful information about the direction and magnitude of expected deviations of the MRTS data from their historical dynamics and, thus, help to improve our high-frequency estimate of $\rho(L)$\footnote{For another example of the use of dynamic factor model methods for the purpose of benchmarking to official statistics, see \cite{Brave et al. 2021}.}}. This slight modification leads to an exactly identified model as well as modest gains in our ability to nowcast the MRTS data. This is because the additional covariances contain useful information about the direction and magnitude of expected deviations of the MRTS data from their historical dynamics and, thus, help to improve our high-frequency estimate of $\rho(L)$\footnote{M$_{0}$ corresponds to retail and food services sales ex. auto from the MRTS in December 2017. At the moment, the SafeGraph series only begins in January 2019. An unbalanced panel for estimation is not a concern for models of this type and just requires that a small modification be made to the Kalman filter as described in \cite{Brave et al. 2020}.}

Once the model has been estimated, to arrive at a weekly level of spending that is benchmarked to the MRTS data, we construct the weekly index $I_k$ from the Kalman smoothed estimate of the weekly latent factor as:

$$I_k = \exp \left( M_0 + \sum_{j=1}^{k} F_j \right),$$

where $k$ references the number of weekly observations for the index, $k = 1, ..., K$, and $M_0$ is the level of Census sales in the base period. Given the triangle average restrictions, the monthly average of the weekly index will approximately equal the monthly MRTS data, with the small difference attributable to the log transformation and the use of a monthly value, $M_0$, to initialize the index. Given data availability constraints, we are only able to produce an index that begins in the first week of January 2018\footnote{M$_{0}$ corresponds to retail and food services sales ex. auto from the MRTS in December 2017. At the moment, the SafeGraph series only begins in January 2019. An unbalanced panel for estimation is not a concern for models of this type and just requires that a small modification be made to the Kalman filter as described in \cite{Brave et al. 2020}.}

### 3.3 The Estimated Index

Figure\footref{fig:weekly_index} shows our Weekly Index of Retail Trade as a seasonally adjusted monthly spending rate in comparison to retail and food services sales ex. autos from the MRTS over our entire
sample (upper left) and some selected sub-sampled time periods. The gray shading plots the number of newly diagnosed Covid-19 cases in the U.S. Several interesting features appear in the weekly index that are not readily apparent in the MRTS data. First, weekly sales in March 2020 were very uneven, rising substantially in the first half of the month and then plummeting in the second half (upper right). This is consistent with consumers’ increasing awareness of the Covid-19 virus in mid-March ([Keane and Neal 2021]) and anecdotal evidence of “stockpiling” just prior to the closure of nonessential businesses across much of the U.S. in the second half of March. These closures and the accompanying stay-at-home orders issued by many states and locales then coincides precisely with the sharp decline in the index in the latter half of March.

Subsequently, the weekly index begins to recover around mid-April 2020, as local communities lifted stay-at-home orders and the federal government expanded unemployment insurance and disbursed the first round of economic impact payments. In contrast, in the MRTS the impact of these developments are not apparent until the May data. Note, too, that the advance estimate of the May MRTS was published in mid-June, whereas the first estimate of the index for the second half of April was produced at the beginning of May. Accordingly, the weekly index identified the rebound in sales well in advance of the MRTS.

The recovery continued throughout the summer months of 2020, with the index returning to pre-pandemic levels by July 2020. However, as the figure shows, the recovery was not without some variation at the weekly frequency. In particular, when new cases of Covid-19 began to rise again during the summer, the index exhibited periods of decline in both July and August (lower left). This drop-off is not apparent in the MRTS data, because they average in the weeks of substantial positive growth both before and after the peak of the summer wave of cases.

The index also highlights the uneven nature of sales during the fourth quarter of 2020 and into the first quarter of 2021 (lower right). Sales fell sharply starting around Thanksgiving, corresponding to the resurgence in Covid-19 cases. Sales remained at a low level through
much of December, but then improved markedly around the turn of the year during the week when many Americans received their second round of Covid-19 stimulus payments. But after that initial burst, sales fell sharply again, driven in part by severe winter weather across much of the U.S. in February and then recovering by the first week of March.

As a policy-relevant application of our weekly index, figure 3 compares the week-to-week movements in the index in 2020-21 against their similar 2018-19 averages. The vertical dashed lines mark weeks when each of the initial disbursements of each of the three rounds of economic impact payments over the past year took place—the CARES Act in April 2020, the CRA in January 2021, and the ARP in March 2021. We can see a clear connection between stimulus payments and retail spending, with sales jumping during all three episodes. While the impact of the latter payments on retail sales are apparent in the MRTS as well (see figure 2), the CARES Act payments in April are not because the MRTS data is only available at a monthly frequency.

Overall, our weekly index reveals patterns in retail sales that are of interest to those studying the impacts of the pandemic and the policy responses to it that are not always visible in the MRTS data. Moreover, we do so in a way that preserves the representative structure of the MRTS.

Our model’s combination of time series and benchmarking to the MRTS also provides a more stable reading of activity than two alternative measures of weekly retail sales, one from the Bureau of Economic Analysis (BEA) and one from the Opportunity Insights (OI) lab. These measures also use credit and debit card data, but both come from a single data provider with different coverage and use different statistical methods than our index.

This is seen in figure 4, which plots the series as a percent deviation from a pre-pandemic January 2020 baseline. All three indexes generally track one another, but ours is sub-

---

25 See Aladangady et al. (2019) and Dunn et al. (2020) for more detail on the underlying data and construction of the BEA card spending estimates based on data from Fiserv First Data. Monthly and weekly data are available at https://www.bea.gov/recovery/estimates-from-payment-card-transactions. The OI estimates are based on data from Affinity Solutions and are described in more detail in Chetty et al. (2020). Daily and weekly data are available at https://www.tracktherecovery.org/.

26 In addition, the BEA and Opportunity Insights measures include spending on automobiles and car parts
stantially less volatile.\textsuperscript{27} This suggests that using information from a range of data sources could do a better job at extracting the underlying trend in overall retail activity than any individual data series. For example, the OI measure described in figure 1b of Chetty et al. (2020) has a root mean-squared error of close to 5 percentage points in comparison to the Advance Monthly Retail Trade Survey (MARTS), whereas our indicator’s RMSE is only 1.4 percentage points. As we show below, there is substantial variation over time in the contributions of different indicators to explaining the common factor in overall retail sales, which our multivariate structure exploits to produce superior forecasts of the MARTS.

### 3.4 Contributions of Components to the Weekly Index

Figure 5 plots the contribution of each individual indicator to our overall index for every week in our sample. The variation in the index that cannot be explained by the weekly series is attributed to the MRTS data; in turn, this contribution largely reflects the temporal aggregation constraint imposed on the mixed-frequency dynamic factor model. The figure highlights the wide and time-varying range of contributions from these different elements. For example, while the dynamics generated by the MRTS (dark blue) often are quite important, they fall short in accounting for the depth of decline of the index in March and contributed little to the rebound in April. At these times, the EIA (purple), and Consumer Edge (orange) data made substantial contributions to the index.

Table 1 decomposes the variance of the weekly growth rate of the index into the percentages explained by each of our six high-frequency data sources and the MRTS data over the January 2018-February 2021 period. The first column presents the results for the index depicted in figure 5, which is produced by the Kalman smoother. Almost 59 percent of its variation is explained by the MRTS, leaving about 41 percent to be explained by the

\footnote{One caveat is that our index excludes auto sales, a component of retail sales known to be somewhat more volatile than other components of retail spending. Both the BEA and OI index include auto sales.}

\footnote{(NAICS code 441) and exclude either gas station sales (BEA) or in some instances groceries (OI). Our Weekly Index of Retail Trade excludes autos. Both the BEA and OI data also use weeks defined as seven-day intervals starting from January 1 of each year. Our Weekly Index of Retail Trade instead uses the week definitions laid out above in section 3.1.}
high-frequency data. Of these data sources, the EIA data explain about 30 percent. While important for a number of specific episodes, together on average the transaction data only explain roughly 7 percent of the variation in the index, with the remaining roughly 4 percent accounted for jointly by SafeGraph and Morning Consult.

To assess the degree of uncertainty around the values in table 1 we perform a leave-one-out cross-validation exercise, re-estimating the model each time dropping one of the weekly data series. This produces a range of values showing the impact of omitting each weekly data source one-by-one. In this way, we can capture interdependencies in the estimation of our model. The lower and upper bounds of these ranges are shown in table 1 in brackets. Overall, this exercise suggests that the MRTS data explains no less than 59 and no more than 80 percent of the variation in the growth rate of our weekly index.

The Kalman smoother uses data from the entire sample to inform the index in any given period. Of course, in real-time analysis, data for \((i, t)\) and beyond are unknown. To gauge the influence of this future information, the second column of table 1 presents variance decompositions for the Kalman (forward) filtered index, which is the expectation of the index’s growth rate based on the data in hand prior to \((i - 1, t)\).\(^{28}\) This decomposition is substantially different from that for the smoothed index. Here, the Safegraph data explain about 36 percent of the variation, and the EIA, Womply, and Morning Consult data also make important contributions. In contrast, the MRTS data explain very little, suggesting that much of their impact on the smoothed index comes from the constraint matching it to the MRTS data at the monthly frequency.

The filtered decompositions also are useful because they give us a sense of how the model may be expected to perform in forecasting the MRTS. The third column of table 1 shows a variance decomposition of nowcasts for the months of March 2020-February 2021 taken from an out-of-sample forecasting exercise with our model. Viewed through this lens, the importance of each high-frequency data source is more balanced. At 27 percent, the

\(^{28}\)Data from after \((i, t)\) are still used in estimation of the model parameters.
SafeGraph data still account for the largest share, but the contribution of the MRTS, EIA, Consumer Edge and Womply indices are all in the range of 14 to 18.5 percent and Morning Consult contributes nearly 9 percent. We now turn to describing this nowcasting exercise in more detail.

4 Nowcasting the MRTS

Our results so far suggest that the mixed-frequency dynamic factor model could be a useful tool for predicting retail sales. We examine this question in a nowcasting exercise that iteratively re-estimates and forecasts in a fashion meant to mimic the real-time construction of the index during the pandemic period. We then compare its predictions for the Advance Monthly Retail Trade Survey (MRTS) against consensus forecasts available at the time and real-time monthly autoregressive forecasts.

4.1 Constructing Out-of-Sample Predictions

To nowcast the MRTS measure of retail and food services sales excluding autos, we use recursive estimates of the Kalman filter to project the weekly latent factor forward in time and obtain the resulting nowcast for month $T$, $M_{t=4,T}$. Forecasts can be made $h$ weeks ahead of each MRTS release, where $h = 0, 1, 2, 3, \text{or } 4$.

Our procedure needs to account for the fact that even when we observe all of the weekly data for a month ($h = 0$), the MRTS data are not yet observed. This means that we cannot fully infer the current month’s error structure, or $\eta_{t=1:4,t=T}$ and $\Sigma$ to be precise. To do so, we use the simulation smoother of Durbin and Koopman (2012). This procedure allows us to account for the impact of data revisions by augmenting the errors in the draws of the estimated end-of-sample variance of the model’s latent states to reflect historical differences between the advance and final releases of the MRTS using data from the St. Louis Fed’s ALFRED database to calculate the variance...
us to simulate multiple paths for the Weekly Index of Retail Trade by taking draws from a multivariate normal distribution of the model’s shocks, and so produce coverage intervals as well as point forecasts. To obtain the intervals, we take percentiles of the distribution of $M_{i=4,T}$ from 1.5 million simulated paths.

### 4.2 Out-of-sample Performance

We evaluate the out-of-sample forecasting performance of our nowcasts by comparing them to consensus forecasts available at the time and to predictions from a monthly autoregressive forecast of the MRTS data. The exercise could help reveal if our index suffers from overfitting, which clearly is a risk given our short sample period and the number of parameters in the model.

For our first out-of-sample exercise, we consider previous forecasts of MARTS when all available weekly data through the end of the month are known, $h = 0$. We seasonally adjust all data with the seasonal factors estimated at the time, iteratively re-estimate the model with real-time values, and produce nowcasts for the MARTS releases between March and February 2021.

Figure 7 decomposes our MARTS nowcasts into the contributions from each of the high-frequency data sources and the lagged MRTS data. For ease of viewing, we present the data only in terms of month-over-month percent (log) changes. The figure highlights the wide and time-varying range of contributions from the different components that we also saw for the smoothed index in figure 5. For example, the improvement in January 2021 retail sales was principally driven by an increase in credit card spending and gasoline consumption. In contrast, last March and April the mobility and consumer sentiment data made outsized contributions to the forecast. In addition, notably, the lagged values of MRTS played a substantial role only in the May and June 2020 and February 2021 nowcasts. This variation over time in contributions to the index highlights the value of using a multi-variate model as
opposed to relying on a single indicator to gauge the evolution of aggregate retail activity.

Table 2 reports mean absolute error ratios comparing the $h = 0$ nowcasts (now expressed as simple month-over-month percent changes) against the median projections from two weekly consensus surveys taken on the Fridays prior to the release of the MARTS data during our sample period: Informa Global Markets (MCM Research) and Action Economics. Values less than 1 (greater than 1) in the table denote that our models produced a lower (higher) mean absolute error for the pandemic period.

We report two ratios for each comparison, with the first calculated based on the initial release of the MARTS data being nowcast and the second based on the MRTS data published as of February 17, 2021. The latter accounts for revisions to the MARTS data, which occur in the two months following the initial release. To establish statistical significance for the comparisons, we use the equal mean absolute error test proposed by Diebold and Mariano (1995) with the small sample size correction of Harvey et al. (1997) and standard errors computed with the Bartlett kernel with lag length set equal to sample size as suggested by Kiefer and Vogelsang (2005).

As seen in table 2, the nowcasts of the month-over-month percent change in the MARTS data outperform the consensus forecasts made during the pandemic by about 60 percent, for both surveys and releases of the Census data. Moreover, even with only ten observations, the Diebold-Mariano test indicates that these differences are significant at the 95 percent confidence level. Thus, the nowcasts have a large and economically significant informational advantage relative to the surveys. This is true even abstracting from March-June 2020, where the informational gains are the largest.

We can also characterize the informational advantage provided by the high-frequency data over and above the MRTS data. To do so, we compare the accuracy of our nowcasts against one-month ahead forecasts from first-order autoregressive models for the MRTS. We consider

\[31\text{The data also undergo an annual revision that is published in April.}\]
\[32\text{One caveat is that we do not account for possible revisions to the high-frequency data. Note too that the results are slightly worse for a version of the model with a diagonal } \Sigma.\]
two such specifications. The first estimates the model parameters using data from January 2006 through February 2020 and holds them fixed when producing forecasts for March 2020 through February 2021. The second instead recursively updates these parameters by adding the previous month’s data to the estimation sample.

To capture the real-time data flow within each month, we produce five nowcasts based on the number of weeks of the high-frequency data available. Given the mid-month calendar release of the MARTS and the lags in the availability of the high-frequency data, there is typically at most only one week of high-frequency data available for the current month at the time of release for the previous month’s MARTS data. This situation corresponds to either the $h = 3$ or $h = 4$ nowcast. Starting from this baseline, we can then track the relative importance of each subsequent week’s worth of data.

Table 3 demonstrates that our dynamic factor model outperforms a monthly AR(1) specification for the MRTS by about 10-30 percent when no weekly data are used in the model ($h=4$) and an even greater 45-55 percent when only 1 week of high-frequency data is used in the model ($h = 3$). The gains steadily increase from there, peaking at about 75-80 percent when all four weeks’ worth of high-frequency data are used ($h = 0$) in the model.

4.3 Sources of Forecast Error

While this forecasting performance is impressive, several potential sources of forecast error in our model are worth noting.

1. **Sampling error**: The high-frequency spending data we use collectively account for only a small fraction of the universe of retail sales covered by MRTS and the data are not representative of the universe of retail transactions. Our methodology attempts to address this issue by including more representative data from EIA and Morning Consult in the model and forcing our index to match the MRTS at the monthly frequency. Nonetheless, these corrections are not perfect, and a portion of our forecast errors will be caused by these differences in coverage.

2. **Parameter instability**: The wide variation in the data during the first few months of the pandemic mean that period will have an outsized effect on identification. This is an issue for all forecast models estimated over this period. Indeed, between March
and June our parameter estimates jumped around considerably before settling down to relatively consistent values in the months since then. This parameter instability is another potential source of forecast error, especially for the relatively larger misses of our model in the March-June period.

3. **Census seasonal factors and revisions**: The seasonal factors we use to adjust the weekly spending series are directly proportional to the MRTS seasonal factors (see Appendix). Since the MRTS seasonals are re-estimated concurrently, we must forecast them prior to the MARTS release. Any error in this forecast can propagate into our nowcasts. So, too, can large revisions to past values of the MRTS. And in fact, at times during the pandemic both the errors in seasonal factor forecasts and revisions to past MRTS data have been extremely large by historical standards.

Figure 8 decomposes our forecast errors \((h = 0\) nowcasts minus actual) during the pandemic into each of these three sources. To create this decomposition, we re-ran our nowcasts under alternatives that altered the real-time exercise by using: 1) the model parameters estimated at their latest values, and 2) the latest MRTS data and seasonal factors. Differences between the resulting nowcasts and our original estimates are informative on the roles of parameter instability and data revisions in explaining our errors; the residual is then attributed to sampling error.\(^{33}\)

Parameter instability played a large role in explaining forecast errors in the early months of the pandemic. As our parameter estimates have settled down since July 2020, this particular source of error has become less impactful, with the exception of January 2021. In contrast, revisions to the Census data and seasonal factors typically played a minor role, with the notable exception of March 2020. The large error in our forecast for the monthly seasonal factor, which is due to a large change in the Census seasonal factor, caused us to underestimate the decline in retail sales in March. At the same time, several of the underlying weekly data series overestimated the March decline and the two sources of forecast error largely canceled each other out.

Overall, the errors in our nowcast are largely driven by sampling variability attributable to differences in the coverage of our high-frequency data sources and the MRTS. This was most evident in the early stages of the pandemic in March and June 2020, but was also true

\(^{33}\)At the time of writing, the January and February 2021 MRTS values were still subject to further revisions.
at the end of 2020 when retail sales declined more than our model expected in October and November. Similarly, our largest misses in January and February 2021 were also primarily attributable to sampling variability.

All together, the mean absolute error for our nowcasts during the pandemic is 1.2 percentage points. This is against an average absolute percent change in retail and food services sales ex. autos of 4.9 percent over this period. June and November 2020 and January and February 2021 are the only months in our sample where our absolute errors are greater than 1 percentage point; excluding those four months, the mean absolute error of the other eight months was just 0.2 percentage point, versus an average absolute change in retail and food services sales ex. autos of 4.8 percent.

5 Conclusion

We used weekly measures of revenue, credit and debit card transactions, consumer sentiment, mobility, and gasoline shipments to create a seasonally adjusted Weekly Index of Retail Trade that is benchmarked to monthly retail and food services sales (excluding automotive spending) from the Census Bureau’s Monthly Retail Trade Survey (MRTS). To do so, we use a novel mixed-frequency dynamic factor model that combined the valuable real-time information from alternative high-frequency data sources of consumer activity with the representative sampling of the MRTS.

Using our weekly index, we showed that retail sales during the Covid-19 pandemic in the U.S. were highly variable at the weekly frequency, with a considerable amount of interesting variation masked at the monthly frequency by the MRTS. The weekly spending patterns that we document align well with the timing of the waves of Covid-19 cases, restrictions imposed on businesses and households, and economic impact payments that we have seen during the course of the pandemic.

In addition, we found that the mixed-frequency dynamic factor model used to create our
weekly index could be reliably used to nowcast the Census Bureau’s Advance Monthly Retail Trade Survey (MARTS) in real time, besting by about 70 percent both consensus forecasts available at the time and forecasts from monthly autoregressive specifications for the MRTS in terms of lower mean absolute error.

Going forward, our methodology can be extended to include finer levels of disaggregation, both geographically and by sales categories. For example, the Census Bureau has recently begun to release monthly state-level retail spending measures. Insofar as the high-frequency data sources we used can be disaggregated to the U.S. state level, estimating similar models for state retail sales would be a straightforward extension of our analysis.

Furthermore, we focused on the retail and food services sales ex. autos category of spending, but other categories of consumer spending may also prove to be forecastable. Tailoring our model to the sub-aggregates used by the BEA may be useful for forecasters and others interested in mapping at a high frequency into GDP the effects of pandemics and future business cycles on consumer spending.

*Note:* This table shows mean absolute errors (MAEs) for nowcasts of retail & food services sales ex. auto from our mixed-frequency dynamic factor model relative to monthly autoregressive specifications estimated over a fixed and recursive window each with 1 lag. The fixed-window model was estimated over a sample period from January 2006 through February 2020 and its coefficients held fixed to produce one-month ahead forecasts over the period from March 2020 through December 2020. The recursive-window model adds one month of data to the estimation sample iteratively from March 2020 through January 2021 and uses the updated model coefficients to produce one-month ahead forecasts. To produce similar forecasts from our mixed-frequency dynamic factor model we estimate the model separately including from zero to four weeks of available weekly data for the month being nowcasted. The markers */** denotes statistical significance from a Diebold-Mariano test of equal mean absolute error (i.e. ratios equal to 1) at the 95% confidence level using the Bartlett kernel with lag length equal to sample size and a small sample size correction. Retail & food services sales ex. auto data used to construct mean absolute errors were obtained from Haver Analytics.
Figure 1: Weekly Data Series, by Source

Source: Authors’ calculations based on data from the U.S. Census Bureau and Energy Information Administration, Consumer Edge, Womply, Facteus, Morning Consult, and SafeGraph.

Note: Daily data are aggregated to weekly and seasonally adjusted with the procedure described in the appendix. All of the data series as shown in the figure are set equal to 100 in January 2020.
Figure 2: Retail and Food Services Sales ex. Auto

Source: Authors’ calculations based on data from the U.S. Census Bureau and Energy Information Administration, Consumer Edge, Womply, Facteus, Morning Consult, and SafeGraph.

Note: We align the monthly MRTS data to the second week of each month to emphasize the temporal aggregation constraint that requires the monthly average of our Weekly Index of Retail Trade to approximately equal the MRTS data. The gray shaded area represents the weekly average of new Covid-19 cases in the United States for various time periods.
Figure 3: Weekly Retail Sales and the Timing of Economic Impact Payments

Source: Authors’ calculations based on data from the U.S. Census Bureau, Energy Information Administration, and Department of the Treasury; Consumer Edge, Womply, Facteus, Morning Consult, and SafeGraph.

Note: The figure compares week-over-week percent changes in our Weekly Index of Retail Trade over the 2020-21 period relative to the average of the same weeks of 2018 and 2019 in order to highlight the impact of the various rounds of Economic Impact Payments on retail and food services sales ex. auto. The first vertical line corresponds to April 10, 2020, when the CARES Act funds were initially disbursed; the second to January 6, 2021, when the second round of payments authorized in the 2020 year-end omnibus federal spending bill were deposited; and the third line to March 17, 2021, the date when the payments authorized in the American Rescue Plan were initially disbursed. All initial payment disbursement dates were determined from the U.S. Treasury’s Daily Treasury Statement using data from Haver Analytics.
Figure 4: Weekly Measures of Retail and Food Services Sales

Source: Author’s calculations. Bureau of Economic Analysis and Opportunity Insights were obtained via Haver Analytics.

Note: The figure compares relative to a pre-pandemic baseline three weekly measures of retail and food services sales: our Weekly Index of Retail Trade and two different measures of credit and debit card spending from the U.S. Bureau of Economic Analysis (BEA) and the Opportunity Insights (OI) lab.
Figure 5: Contributions to Growth for the Weekly Index of Retail Trade

Source: Authors’ calculations based on data from the U.S. Census Bureau and Energy Information Administration, Consumer Edge, Womply, Facteus, Morning Consult, and SafeGraph.

Note: The contributions sum to the Kalman smoothed estimate in each week of the percent (log) change of the Weekly Index of Retail Trade. The method of calculation for these contributions is described in detail in Brave, Butters, and Kelley (2020).
Figure 6: February 2021 Nowcast for Retail and Food Services Sales ex. Auto

*Source:* Authors’ calculations based on data from the U.S. Census Bureau and Energy Information Administration, Consumer Edge, Womply, Facteus, Morning Consult, and SafeGraph.

*Note:* The figure shows our February 2021 nowcast using weekly data available through the first week of the month. The shaded regions represent 70% (dark gray) and 90% (light gray) coverage intervals.
Figure 7: Contributions to Growth for our MARTS Nowcasts

Source: Authors' calculations based on data from the U.S. Census Bureau and Energy Information Administration, Consumer Edge, Womply, Facteus, Morning Consult, and SafeGraph.

Note: The figure displays contributions to our MARTS nowcasts for March 2020 through January 2021 using the weekly data available through the end of each month and previously released MRTS data. The contributions in the figure sum to the nowcast value by construction.
Figure 8: Nowcast Error Decomposition

Source: Authors’ calculations based on data from the U.S. Census Bureau and Energy Information Administration, Consumer Edge, Womply, Facteus, Morning Consult, and SafeGraph.

Note: The total nowcast error is defined as the (revised) MRTS value minus our model’s nowcast. The portion of the forecast error attributed to parameter instability is defined as the difference between the nowcast and the value from an alternative nowcast where our model parameters have been fixed at their current estimates. The error due to Census revisions is defined as the difference between the alternative nowcast with the fixed model parameters and another alternative nowcast that uses both the fixed parameters and the revised, rather than real-time, MRTS data. We attribute the remaining nowcast error to sampling variation, such that all three sources of error sum to the total nowcast error.
7 Appendix

7.1 Seasonal Adjustment of Weekly Data

Seasonal variation is large in retail sales, yet none of the high-frequency data are available on a seasonally adjusted basis. Standard seasonal adjustment procedures, such as the X13 ARIMA-SEATS program published by the Census Bureau (U.S. Census Bureau [2017]), are not well suited to the seasonal adjustment of high-frequency data series. In our case, we are also handicapped by the very short history of our time series. For instance, the method described in Cleveland and Scott (2007) that is commonly used to seasonally adjust weekly time series like unemployment insurance claims requires much more than the roughly two years of data that we have available to us.

However, we are still able to seasonally adjust our weekly data by making. First, we assume that the seasonal factors for our weekly data when temporally aggregated to the monthly frequency are the same as the MRTS seasonal factors. Second, we assume that the weekly seasonal factors are a specific function of the monthly seasonal factor, the number of days in the week, and a week-of-the-month effect.

Below we describe how the MRTS seasonal factors can be used to seasonally adjust the high-frequency data sources at a first pass. This procedure reliably removes the majority of seasonal patterns in our transaction and foot traffic data (the EIA data are already seasonally adjusted using the Cleveland and Scott (2007) method by Haver Analytics and the Morning Consult data do not exhibit seasonality). To then account for any residual seasonality in the data, we remove prominent week-of-year effects.

Derivation of the Weekly Seasonal Factors

To account for seasonality in the high-frequency data, we incorporate the monthly seasonal factors from the Census Bureau’s retail and food services sales ex. autos series.\footnote{The seasonal factor for month is defined as , where is the seasonally adjusted Census series and is the unadjusted Census series.} We assume
that the observed monthly Census seasonally adjusted (SA) and non-seasonally adjusted (NSA) time series are the sum of latent (unobserved) weekly series:

\[
\sum_{i=1}^{4} C_{i,t}^{NSA} = C_{t}^{NSA} \\
\sum_{i=1}^{4} C_{i,t}^{SA} = C_{t}^{SA}
\]

where \( C_{i,t}^{NSA} \) and \( C_{i,t}^{SA} \) are NSA and SA weekly Census retail sales, \( C_{t}^{NSA} \) and \( C_{t}^{SA} \) are NSA and SA monthly Census retail sales, and the subscripts \( t \) and \( i \) index months and weeks, respectively.

The seasonal factors are multiplicative in levels (additive in logs) at both the weekly and monthly levels

\[
C_{i,t}^{SA} = C_{i,t}^{NSA} \cdot SF_{i,t}^{C} \\
C_{t}^{SA} = C_{t}^{NSA} \cdot SF_{t}^{C}
\]

where \( SF_{i,t}^{C} \) is the latent weekly Census seasonal factor and \( SF_{t}^{C} \) is the monthly Census seasonal factor. Together with our assumption that monthly Census retail sales are the sum of latent weekly sales, this yields the following relationship between the monthly and weekly data and seasonal factors:

\[
C_{t}^{NSA} \cdot SF_{t}^{C} = \sum_{i=1}^{4} C_{i,t}^{NSA} \cdot SF_{i,t}^{C} \\
\Rightarrow SF_{t}^{C} = \sum_{i=1}^{4} \frac{C_{i,t}^{NSA}}{C_{t}^{NSA}} \cdot SF_{i,t}^{C} \\
\Rightarrow SF_{t}^{C} = \sum_{i=1}^{4} \left( \frac{C_{i,t}^{NSA}/D_{i,t}}{C_{t}^{NSA}/D_{t}} \right) \frac{D_{i,t}}{D_{t}} \cdot SF_{i,t}^{C}
\]
where $D_{i,t}$ is the number of days in week $i$ of month $t$ and $D_t$ is the number of days in month $t$. The first term in the sum of the last expression is the ratio of sales per day in week $i$ to sales per day in the month. This will reflect week fixed effects. For example, weeks 2 and 4 may have greater sales because they coincide with pay periods. The second term is the ratio of days in the week to days in the month – in our week dating scheme, the last week of the month has a variable number of days, and this adjusts for the fact that weeks can make up a different share of the total days in the month across months of different length.

The goal of the weekly Census seasonal factor, $SF^C_{i,t}$, is to offset these two calendar sources of weekly sales variation. This suggests setting the weekly seasonal adjustment factors according to the formula:

$$SF^C_{i,t} = \frac{1}{4} \frac{1}{\text{avg}_{i,t}} \left( \frac{C_{i,t}^{NSA}}{D_{i,t}} \right) \left( \frac{C_{t}^{NSA}}{D_{t}} \right) \cdot SF^C_t$$

Here, $\text{avg}_{i,t}$ refers to the average of the ratio of sales per day in week $i$ to sales per day in the month (averaging over some window of months).

We can perform a related exercise to seasonally adjust the high-frequency data. We exploit this structure and the Census monthly seasonal factors to set weekly seasonal factors for $HF_{i,t}^{NSA}$, the NSA high frequency weekly retail sales data, in order to create a SA series, $HF_{i,t}^{SA}$:

$$SF^{HF}_{i,t} = \frac{1}{4} \frac{1}{\text{avg}_{i,t}} \left( \frac{HF_{i,t}^{NSA}}{D_{i,t}} \right) \left( \frac{HF_{t}^{NSA}}{D_{t}} \right) \cdot SF^C_t$$

$$HF_{i,t}^{SA} = HF_{i,t}^{NSA} \cdot SF^{HF}_{i,t}$$

$$HF_{t}^{SA} = \sum_{i=1}^{4} HF_{i,t}^{SA}$$

40
where $SF_{i,t}^{HF}$ and $SF_{t}^{HF}$ are weekly and monthly seasonal factors and $\text{avg}_{i,t}$ is taken over all of the week $i$'s of month $t$ in the data sample (for which we have a complete month of data). Averaging the weekly sales share ratios at the week-by-month level allows us to control for varying distributions of sales within the month, which are most noticeable during specific times such as the end-of-year holiday period.

Our approach still has several implementation issues, for example whether or not to include holidays in the $D_{i,t}$ and $D_{t}$ variables. Through testing, we found that the more parsimonious approach - including the holidays - produced better results than only including non-holiday days in the formulas. In addition, $SF_{t}^{C}$, the monthly Census seasonal factor, is not available until the MARTS is published, and so we must estimate it for our nowcasting work. The Census Bureau seasonally adjusts retail sales on a concurrent basis; that is, every month they re-rerun their programs and estimate new factors with all the available data. These programs produce forecasts for future seasonal factors, which the Census Bureau publishes for the closely related retail and food services sales category. Accordingly, we forecast $SF_{t}^{C}$ with a regression using this seasonal factor and 12 lags of the seasonal factor for our sub-aggregate. In practice, this produces accurate forecasts of $SF_{t}^{C}$ with one exception, when Census substantially revised their seasonal factors in March 2020 at the onset of the pandemic. To illustrate, over the nine-month period from January 2020 through September 2020, the mean absolute percent error for our forecasts of the monthly Census seasonal factor was 2.6%. However, excluding the month of March reduces this to just 0.6%.

**Residual Seasonality**

Even after implementing the seasonal adjustment procedure described above, several of our weekly data series still contain a degree of residual seasonality. Residual seasonality is a phenomenon where there is a predictable seasonal pattern left over in a data series that has already been seasonally adjusted by some standard procedure (Consolvo and Lunsford, 2019). The residual seasonality in the various weekly data series that we use are most
noticeable during the end-of-year holiday period, where there is often a predictable pattern in the weekly growth rates around the first week of the year. This could arise, for example, because the seasonal spending patterns for credit and debit card transactions do not exactly mirror the seasonal pattern in the Census retail sales measure as assumed above.

To account for residual seasonality, we regress each of the spending and foot traffic series, in log growth rates, on a constant and regressors for important retail holidays that move within the year, such as Easter and Thanksgiving, as well as individual week dummies for a small set of important weeks that we identified for each individual series. To get the series back to levels, we take the residuals from these regressions, add back in the mean growth rate taken out by the constant in the regression, and cumulate them forward from the series’ initial log-level. We then exponentiate the series to get it back into natural units. We do not find evidence of any seasonality in the consumer sentiment data and, therefore, do not seasonally adjust it.
